Just as the International Code of Nomenclature for algae, fungi, and plants covers all groups traditionally studied by botanists, so the International Code of Zoological Nomenclature (International Commission on Zoological Nomenclature, 1999) embraces all that have been considered by zoologists. Although the two Codes both arose in the mid-nineteenth century, their provisions have diverged in some significant ways through subsequent modifications. The first zoological Code appeared in 1843, and revisions were considered at each International Congress of Zoology until these were discontinued after 1972. New editions are now prepared more irregularly. The starting point for zoological nomenclature is the 10th edition of Linnaeus' *Systema Naturae* published in 1758; there are no exceptions for particular groups.

The zoological and algal, fungal, and plant Codes rule that they are independent. This means, for example, that the same generic name can be used for disparate organisms provided they belong to groups treated under different Codes; a classic case is *Drosophila*, a genus of mushrooms and also one of flies. The occurrence of such cross-Code homonyms can cause confusions in database searching, and the algal, fungal, and plant Code now recommends that taxonomists publishing new generic names should not use ones already existing in zoology.

The zoological Code is distinctive in operating the principle of coordination of ranks. Three series of names are recognized as coordinate: family-, genus-, and species-groups. Each group includes names of several ranks, for example, species includes superspecies, species, and subspecies; these are treated as equivalent for nomenclatural purposes, such as assigning priority of publication and author citations. No rules relating to names above the family-group level are included.

The description or diagnosis accompanying the publication of new scientific names in zoology can be in any language that uses words, although English, French, German, Italian, or Latin are recommended. Surprisingly, the designation of name-bearing types, although recommended, was not made mandatory until the 1999 edition of this Code. In contrast to the other Codes, a name-bearing type can represent the “work of an animal” rather than the organism itself, for example a bite mark left by an animal in a leaf. Further species names in which the generic name and specific epithet are identical, for example, *Troglodytes troglodytes*, termed tautonyms, are permitted in zoology but not in the other Codes.

There are also differences when a species is moved from one genus to another. In zoology, the earliest name takes precedence and is to be taken up in the new genus even if an identical name based on a different name-bearing type already exists in the genus; in this way, secondary homonyms can be created.

In order to minimize the disruption of names, this Code rules that names which have not been adopted after 1st

Table 2 Equivalent terms used in the current Codes of nomenclature (excluding the PhyloCode)

January 2000 cannot take precedence over a different name in current use; there are stringent guidelines as to how names qualify as “forgotten”. Also in the interests of stability, a series of Official Lists are maintained, dealing with names in particular ranks and also particular works. Terminological differences between the different Codes are a particular source of confusion to biologists; the same term can have different meanings and the same concept different terms (Table 2). Proposals to harmonize terminology have been made but have not yet been adopted across the Codes.

The International Commission on Zoological Nomenclature has wide powers to set aside provisions of the Code in particular cases where to follow the rules would lead to changes in well-established names. Applications have to be published in the *Bulletin of Zoological Nomenclature*, and after a period to permit zoologists to publish Comments in the Bulletin, the Commission expresses and publishes an Opinion that is binding. After the long series of International Congresses of Zoology ended in 1973, the Commission has worked to prepare new editions of the Code largely by correspondence and discussions of proposals in the *Bulletin*. New editions are now subject to ratification at a General Assembly of the International Union of Biological Sciences, under whose aegis it operates. Proposals relating to electronic publication, and the requirement that new scientific names must be registered in ZooBank (an online system similar to MycoBank for fungi) in order to be available, are currently under active debate and likely to be implemented in the next edition of this Code.

Interdisciplinary Codes

The Draft BioCode

The need for a more unified approach to biological nomenclature has long been recognized, and this has been of particular concern to the International Union of Biological Science (IUBS). Concerted action to address the problem emerged from a symposium held during the International Congress of Systematic and Evolutionary Biology in 1985. Pressure for harmonization between the various Codes arises from the unification of biology as a discipline and the consequent difficulties in teaching nomenclature, the mismatch between the Codes and the kingdoms of life now recognized, the needs of users for increased stability in names, the needs of systematists to spend less time on nomenclature, and the difficulties faced by developing nations. In addition, the existing Codes were finding that they had to confront similar issues, for example, in relation to electronic publication, living name-bearing types, organisms that could be treated under different Codes depending on whether they were interpreted as animals or plants, protected lists of names, and the registration of newly proposed names.

The move toward harmonization is operating along three fronts: harmonization of terminology (see Table 2), bringing similar provisions into all Codes where new problems are being confronted, and developing a unified Code that would apply to all kinds of organisms. In 1995 the IUBS and the International Union of Microbiological Societies, the two bodies that

between them oversee all five Codes, jointly established an International Committee on Bionomenclature to promote these initiatives. This Committee, which consists of representatives of the bodies responsible for the five organismal Codes, issued a Draft BioCode: The Prospective International Rules for the Scientific Names of Organisms for discussion in 1996, and a revised version was then prepared in 1997. There was little progress toward harmonization made at that time, as the mechanisms for the production of lists of available names and registration were not then available. However, that position has changed as it became increasingly evident that the different Codes had similar issues to contend with, and that there were increasing numbers of cases where there were problems of deciding if particular groups of organisms were a part of botany or of zoology – when they actually belonged to neither the plant nor the animal kingdom. Consequently, in 2009 the International Union of Biological Sciences initiated a program to revise the Draft BioCode (1997).

A revised version of this Code, the Draft BioCode (2011), prepared by a working group of the International Committee on Bionomenclature, and taking note of new developments in technology, was released in December 2010 (Greuter *et al.*, 2011), and was discussed at the International Congress of Systematic and Evolutionary Biology in Berlin in February 2011. That Congress commended the Code for further revision following feedback from individuals, and a new version is anticipated in 2012 for presentation to the upcoming IUBS General Assembly. The BioCode does not aim to replace the current series of Codes, but to provide them with an overarching framework. Some changes in the special Codes will be needed before it can take effect – especially the requirement to register new names and nomenclatural acts, the restriction of diagnoses to English or Latin, and the ability to protect names and their usages by Adopted Lists. These changes to promote common practices and rules are currently in discussion or have been implemented by the different responsible bodies. This Code, in addition to other matters, also seeks to prohibit the same names being available for use for different organisms under the separate Codes, and adopts the zoological Code principle of coordinated status of names within rank groups. It is anticipated that, during the next few years, a finalized version of the *BioCode* will, subject to approval of the appropriately mandated bodies, be proposed for adoption by the International Congress of Systematic and Evolutionary Biology, the International Union of Biological Sciences, and the International Union of Microbiological Societies.

A by-product of the endeavors of the International Committee on Bionomenclature to harmonize terminologies between the different Codes has been the compilation of a glossary of terms. The first draft of 1994 included 1175 terms, which swelled to over 2100 in an extended version, “Terms used in Bionomenclature: The naming of organisms (and plant communities)” (Hawksworth, 2010; also available as a free PDF to download from or interrogate on the website of the Global Biodiversity Information Facility).

The PhyloCode

The advent of molecular systematics has accelerated the elucidation of phylogenetic relationships of organisms, and some

systematists have felt that there is a need for a separate system for the naming of evolutionary lines (i.e., clades) that would allow the use of unlimited numbers of hierarchical categories – and enable the same names to be retained for a particular clade when its rank was changed. If formal scientific hierarchical names were to be given to equivalent branching points in phylogenetic trees, it has been argued that considerable numbers of new ranks would be needed and there would be an exponential expansion in the numbers of such names. This problem is addressed by the PhyloCode (Cantino and De Queiroz, 2010), the International Code of Phylogenetic Nomenclature, the first draft of which was prepared in 2000. This is seen as a complement to the existing Codes, differing fundamentally in being based on the recognition and naming of groups of organisms circumscribed by descent, rather than the linking of names to name-bearing types. At present, the PhyloCode does not make provisions for the naming of species, although different ways in which that might be handled have been proposed.

The content of a taxon is therefore delimited by a definition based on ancestry and uses “specifiers” (e.g., species, specimens, and shared derived characters) to indicate actual organisms. The phylogenetically defined taxon is an ancestor and all of its descendants. The writers of the PhyloCode used the Draft BioCode (1997) in its preparation, and consequently its organization, some of its terminology, and the wording of certain rules are derived from the BioCode. It also envisages a system for the registration of new clade names.

The PhyloCode has occasioned much debate and acrimony among taxonomists, most of whom feel that the hierarchical systems of the other Codes are sufficiently flexible to accommodate the results of phylogenetic studies. The PhyloCode has not been adopted by most taxonomists, including those concerned with elucidating phylogenies, but it may have applications in phylogenetic discussions in cases where the clades are particularly robust. In many groups of organisms, however, the current sampling is so incomplete that these are not well supported and are subject to change as new data sets are included.

Special Cases

Particular provisions or problems in the Codes relate to the special cases of ambireginal organisms, fossils, hybrids, lichens, and pleomorphic fungi.

Ambireginal Organisms

Ambireginal organisms are ones that can be treated under different Codes depending on whether they are considered to be plants or animals, algae or bacteria, etc. The problem is particularly acute in the case of unicellular and often flagellate organisms now placed in the kingdom Protista (or Protoctista or Protozoa), and especially where related species may or may not have chloroplasts and so have traditionally been treated as plants or animals, respectively. Because different rules apply when a plant is found to be an animal, name changes in both the generic and species names may result. For example, the

euglenoid name *Entosiphon* B. Stein 1878 is acceptable under the zoological Code, but when the organism is treated as a plant it has to be replaced by *Entosiphonomonas* Larsen & Patterson 1991, as there is an earlier flowering plant genus *Entosiphon* Beddome 1864.

The resultant frustrations and confusions have led to demands for a separate Code for protist groups, but the preferred route forward is to have parallel provisions in the existing Codes. The problem would not arise under the Draft BioCode as no decisions as to whether an organism is a plant or an animal would be needed as Adopted Lists of Names could be proposed for protection for such organisms.

In the case of slime molds (*Myxomycota*), because these organisms have been traditionally studied by mycologists, they are treated under the International Code of Nomenclature for algae, fungi, and plants; that practice is continued to prevent the disruption in names that a switch to the zoological Code would entail. The *Cyanobacteria*, traditionally treated under what is now the International Code of Nomenclature for algae, fungi, and plants as blue-green algae, are pragmatically best left there rather than transferred to the prokaryote Code in order to avoid unfortunate and unnecessary name changes – although that issue is still contentious and to be addressed by an inter-Code committee.

Fossils

Special provisions for fossils are made only under the International Code of Nomenclature for algae, fungi, and plants. Pieces of trunks, stems, roots, and leaves, and seeds, pollen, and spores can all be given Latinized binomials. These have been considered to be form- or organ- genera and species in the absence of intact plants. Even when such pieces are later found connected together, as in the case of the *Archaeopteris* leaves and *Callixylon* wood, in the past the two systems were often maintained because of the time spans involved. For instance, it is not known whether a *Callixylon* leaf always had an *Archaeopteris* leaf system. However, this provision was deleted from the latest version of the Code (McNeill *et al.*, 2012) so that names based on fossil plant parts are subject to the same rules as other names.

Where names of living and fossil algae, fungi, or plants compete, those of the living one always have precedence. The names of fossils thought to be close but not necessarily identical with a modern genus are often given the suffix *-ites* as in *Ginkgoites* for fossil plants and *Ginkgo* for the single species now living.

Hybrids

Only the International Code of Nomenclature for algae, fungi, and plants has special arrangements for the naming of hybrids. The zoological Code excludes them from consideration.

Under that Code, hybrids can be referred to by indicating their parentage and the use of the multiplication symbol $\times$ to make a hybrid formula. Alternatively, and particularly if the hybrid is regularly encountered in nature, it can be given a separate scientific name prefixed by the same symbol. For example, the hybrid between *Potentilla anglica* and *Potentilla erecta* can be indicated as *Po. anglica* $\times$ *Po. erecta* or

alternatively as *Potentilla* $\times$ *suberecta*. The same principle applies to generic names, for instance, $\times$ *Agroelymus* is a hybrid between species belonging to the genera *Agropyron* and *Elymus*; the name $\times$ *Agroelymus* is called a condensed formula.

In order to be established, the separate names of hybrids have to conform to other parts of the Code that apply to their rank. In the case of condensed formulae for generic names, the parent genera have to be indicated.

Lichens

Although generally appearing as if they were discrete organisms, lichens are mutualistic associations composed of two, or sometimes more, different kinds of organisms. A fungal partner combines with a green alga or cyanobacterium, or both, to form characteristic shapes for the particular association. The different partners, when isolated into pure culture, almost invariably fail to produce the same morphological structures. The classification of both the fungi and algae or cyanobacteria involved is based on their own characteristics and not those of the combined association; both have independent scientific names.

Before the dual nature of lichens was recognized in 1867, and for many years afterward, names were given to the composite lichen structure. The International Code of Nomenclature for algae, fungi, and plants rules that, for nomenclatural purposes, the names given to lichens are to be considered as belonging to the fungal partner alone – and the photosynthetic partner(s) can have separate scientific names. Pedantically, this means that the lichen associations do not have names, only their separate components – so it is impossible to name a lichen.

Fungi

Fungi that have a life cycle with separate sporulating stages, the pleomorphic fungi, have presented a particular problem in naming. In many cases the different stages were first named separately in different genera and were never thought to be connected until fresh research was carried out, for example, by germinating single sexual spores. In many cases the names given to the sexual (teleomorph) and asexual (anamorph) stage have both become well established, and mycologists have been reluctant to simply apply the earliest name regardless of the stage it represents. This resistance is understandable, as it is often a particular sporulating form that is associated with a plant disease or the production of toxins. However, at the International Botanical Congress in Melbourne in 2011, the system of allowing separate names for different morphs of the same fungus species was ended.

Prior to the Melbourne Congress, the Code had ruled that in basidiomycete and ascomycete fungi, with the exception of lichen-forming species, the Code has ruled that the correct name for a fungus with a pleomorphic life cycle that covers all its stages (the holomorph) was that which produces sexual spores, that is, the name of the teleomorph. The anamorph (or anamorphs) were permitted to have independent scientific names that could be used when only those stages are being referred to; the name-bearing types of the names of anamorphs had to represent only the asexual (mitosporic) sporing stage, and the sexual stage must not be mentioned in its establishing

description. For example, when the name *Penicillium brefeldianum* B. O. Dodge 1933 was introduced, the description and type covered both the teleomorph and anamorph; that name is therefore applicable to the teleomorph, even though the generic name *Penicillium* is based on an asexual species. In this case, the teleomorph belongs to the sexual genus *Eupenicillium* and is correctly named *Eupenicillium brefeldianum* (B. O. Dodge) Stolk & Scott 1967. The anamorphic name *Penicillium dodgei* Pitt 1980, with only asexual structures mentioned in its description and represented on the type, was introduced for those wishing to refer just to the asexual *Penicillium* stage. The main reason this system was ended was that molecular techniques now enable the phylogenetic position of asexual fungi to be determined with confidence in overall fungal classifications, in the absence of a sexual stage. The removal of this provision means that the names given to different morphs of the same species now compete on an equal footing. In the example given above, this means that the name *Penicillium dodgei* now has to be treated as a younger synonym of *Eupenicillium brefeldianum*. In order to minimize the potential disruption of a system that had been operating since 1912, the Code instructs mycologists not to take up asexually typified names for species where the sexual names are widely used without reference to the General Committee on Nomenclature (via the Nomenclature Committee for Fungi). Further, the option of developing Lists of approved or rejected names which would receive special protected status and be treated as appendices to the Code was provided. This provision is not restricted to names of fungi with pleomorphic life-cycles, but does exclude lichen-forming fungi.

A further major breakthrough was made at the Melbourne congress in that after 1st January 2013, all newly proposed scientific names of fungi at all ranks have to be deposited in a recognized online repository, along with information required for valid publication (including a description or diagnosis and details of the name-bearing type). The accession number in the database must be cited in order for the name to be validly published after that date. It is the responsibility of the Nomenclature Committee to recognize one or more repositories, and an announcement on this matter is expected during 2012. The MycoBank repository of the International Mycological Association will almost certainly be authorized to carry out this role, but perhaps in conjunction with other indexing centres.

A synopsis of these and some other changes relating to the regulation of fungal names is provided elsewhere (Hawksworth, 2011).

Other Systems

This article focuses on the nomenclatural systems used in and operating under the mandate of internationally mandated committees established by the scientific community. However, in addition to infraspecific systems such as those for special forms of fungi and pathovars of bacteria that are specifically excluded from these Codes, some alternative nomenclatural systems have been proposed, although none has found general acceptance.

A system proposed by Kinman KE in 1994 aimed to take the best from cladistic analyses and include them in a practical

system, with markers used to indicate where orders or higher ranks included organisms belonging to different evolutionary lines (i.e., are paraphyletic) while retaining established names.

More radical is the New Biological Nomenclature, which arose in 1971 out of the frustration felt by Belgian zoologists with the current system of Codes. Names being introduced have to be agreed on by a group of specialists and are presented in Esperanto and not Latinized. Generic names under this system relate more to common perceptions than those of scientists and can embrace several traditionally accepted genera. For example, the New Biological Nomenclature Esperanto generic name *Delfeno* embraces 17 genera of cetaceans; *Delfeno diverskolora* is used for the common dolphin (i.e., *Delphinus delphis*) and *Delfeno ordotipa* for the bottle-nosed dolphin (i.e., *Tursiops truncatus*). The system has not gained general acceptance, but does have an Association devoted to its promotion; detailed rules have been issued, the latest edition in 1991, and 522 names had been officialized by the end of 1990.

A novel approach to the nomenclature of fossils of all groups, a Paleontological Data Handling Code, was proposed by NF Hughes in 1989. Instead of first matching a newly discovered fossil to what has already been described, each specimen is recorded separately with particular reference to its stratigraphic position; only then are comparisons made with what has already been described in that particular position in the fossil record.

Various systems of coding using letters or numbers rather than Latinized names have been proposed, the first by P Hartig in 1871. A particularly elaborate system was that published by G Tornier in 1898, which took the first letters of words of the higher ranks to which a species belongs, followed by a number indicating the particular species; where more than one name started with the same first letter, subscripts were employed. Numerical codes regained popularity in the 1960s in response to the need to compress data in the computing systems in use at the time; one such code extended to 36 digits. With the advances in current technology, the interest in alphanumeric systems has now waned. Humans find it easier to remember words than numbers.

Although concerned with attributing names to assemblages of organisms rather than individual species, attention should also be drawn to the International Code of Phytosociological Nomenclature (Weber *et al.*, 2000), produced under the auspices of the International Association for Vegetation Science. This Code, the first version of which appeared in 1976, governs the allocation of names to plant communities. The names used in this system could be confused with scientific names of organisms, and the rules that control them are based on similar principles to the International Code of Nomenclature for algae, fungi, and plants. The system is hierarchical, and that the names are phytosociological and not organismal can be recognized by their suffixes, which in descending order are -*etum*, -*ion*, -*etalia*, -*etia*, -*etosum*, -*enion*, -*enalia*, and -*enea*.

Why Names Change

Changing scientific names are a constant cause of irritation and frustration to all who use them. That this occurs at all is sometimes interpreted as a criticism of the discipline of

taxonomy, and while that may be justified in some instances, in most cases it is in the long-term interests of users.

New research can show that a certain species is actually a member of a different genus than the one in which it was placed, and it is therefore transferred. Because classifications are predictive of the properties of an organism, accurate placement will benefit users searching for species with particular attributes or wishing to determine the risks they may pose. Detailed studies may also show that one species is a complex of several that merit independent recognition, or that two species currently treated as distinct are really the same; again, these are categories of information that are relevant to users.

Name changes that arise from new taxonomic research, or taxonomic changes, are therefore to be welcomed, but that is not so for nomenclatural changes. Nomenclatural changes, in contrast, are ones that arise from the application of the rules in the Codes, and not from any new scientific data. Two categories of nomenclatural changes can be distinguished. First, some changes are due to a failure to follow the rules of the Codes, for example, the discovery of an earlier name for the same species, that a name did not meet all the requirements for establishment, or, in the case of algae, fungi, and plants, that a name was superfluous when published. Second, some changes arise from rules of the Code itself that are retroactive, for example, in relation to starting point dates or new provisions relating to issues ranging from recommendations on spelling to complete revisions of particular sections.

Problems leading to name changes also arise from the application of the system of name-bearing types. Species names are sometimes found to have come to be applied to a species different from that represented by its type. This category of changes is especially unfortunate as it can mean that a name that has been used in one sense has to be applied in a different one.

The responsibility for deciding when enough data are at hand to justify a change in taxonomy will always lie with the taxonomist. Provided that the taxonomist is self-critical in approach and conscious of the need to be conservative in the interests of the image of the subject, most taxonomic changes will prove to be in the users' interests. That is not the case with nomenclatural changes where all Codes, and particularly the Draft BioCode (2011), are increasingly addressing this fundamental issue. The powers now given to the nomenclature committees and commissions mean that, provided a sound case is made, rules may be set aside to protect familiar names; this can even extend to the designation of different name-bearing types in order to maintain the current usage of names. Unfortunately, not all taxonomists take the route of making formal proposals to Committees to safeguard names, some apparently even taking delight in finding a reason to change a name. This practice is not, however, one condoned by the systematics community as a whole.

Naming Newly Discovered Species

As only about 1.8 million of the estimated 13.7 million species on Earth have yet been given scientific names, the task of naming the balance is one of the major challenges facing

biology in the twenty-first century. However, it is always easier to describe an organism as new to science than to establish if it really has never been described before, albeit in a different genus or even in another family. The repeated unnecessary description of species that are not new is a major cause of the inflation of taxonomic literature. In the case of the fungi, one analysis showed that each accepted species had been on an average described 2.5 times. Once introduced into the body of scientific knowledge, names can never be expunged and will have to be taken note of by all future workers on the group concerned. Before deciding to introduce a new name, careful checking is a prerequisite.

This checking proceeds in a series of steps. First, see if the prospective species matches any in the same (or allied) genera in any checklists for the geographical area from which it comes. Then proceed to any regional or world monographs of the group if they exist. If these steps yield no matches, check names in the world indices of names (*see* Determining Current Names), investigating possible names in allied genera and under names no longer in use. This will entail making lists of possible names and their places of publication, looking up original descriptions, and locating and making comparisons with name-bearing types for likely candidates. If a specialist in the group concerned can be located, that can be a most valuable shortcut as the checking process can be exorbitantly time-consuming if dealing with, for example, a genus of over 1000 described species.

When novelty has been confirmed in the checking phase, the procedures detailed in the appropriate Code for introducing (and in some cases registering) new names must be followed. These include clear statements of why the species is different, a full description (which may have to be in Latin or English), illustrations (photographs as well as drawings are recommended), and a name-bearing type deposited in a secure public institution (ideally with duplicates deposited elsewhere for security). In some groups, molecular sequence data are now being routinely sought to justify the recognition of new species. Publication should ideally be in a journal that will be readily accessible to other specialists in that group and geographical region, although this is becoming less of a problem with electronic publications being made available on the web. Much can be learned from scrutinizing recent publications of new species in the same group by other authors when preparing accounts for publication.

In some instances, notably certain bacteria, internationally developed minimum standards for descriptions are available and should be followed. In some cases codes of practice have been developed, for example, there is one for the description of new fungi developed by the International Commission on the Taxonomy of Fungi.

Determining Current Names

When taxonomic work is undertaken, a number of different names are often found to have been given to the same species. The steps to be followed in determining which is to be used can be considered as a series of sieves, a nomenclatural filter. Although there are differences in the detailed requirements at

each step, and some will depend on the rank, the sequence in which these need to be followed is the same.

Step 1: Publication If a name has not met the requirements for effective publication, either from being printed in a book or journal available to other researchers, or published electronically after 1st January 2012 for algae, fungi, and plants, it need not be considered further.

Step 2: Establishment All of the following requirements must be met: species description (and in some cases illustrations), clarity concerning the rank (or coordinate group of ranks in zoology) and the intention to introduce a new scientific name, registration where appropriate (i.e., for prokaryotes, fungi, and some cultivated plants), citation of the name-bearing type, and in some cases its place of preservation. If any requirement is not fulfilled, those names also need not be considered further.

Step 3: Typification The most critical step and the one that requires scientific judgment is checking the status of the type and examining the specimen, microscopic preparation, illustration, and living culture as appropriate. In some cases, no name-bearing type may have been designated and it may be necessary to select a lectotype or neotype to fix the application of the name. Names whose types are different from the taxon to be named can be excluded at this step.

Step 4: Acceptability Does the name contravene any special provisions, such as being superfluous under the International Code of Nomenclature for algae, fungi, and plants? Is the spelling identical to another name of the same rank (or coordinate group of ranks in zoology)?

Step 5: Precedence What is the date of establishment of each name and which is the earliest in the same rank (in algology, botany, and mycology) or family-, genus-, or species-group (zoology)?

Step 6: Accepted Name The name to be used under the Code will be the one with precedence, that is, the earliest acceptable name to be established in the same rank or group of ranks. This name may have to be used in a new combination. Under the International Code of Nomenclature for algae, fungi, and plants, a new combination cannot be made if the resultant binomial would be spelled exactly like an already existing name (i.e., a homonym). The situation in zoology differs in that a new homonym can be made if the basionym takes precedence by date; the already existing homonym becomes a secondary homonym and can no longer be used. Names applied to the same suprageneric rank or organisms other than the accepted one are synonyms. Synonyms are of two main types: homotypic when based on the same basionym or name-bearing type, and heterotypic when based on different basionyms or name-bearing types. Homotypic synonyms will always appear together, as their applications are irrevocably linked by a common type, whereas heterotypic synonyms may be treated differently depending on the disparate views of taxonomists on the particular types. If the steps potentially result in the disruption of a well-known name, the procedures for the conservation and rejection of names are available as a safeguard (see Principles).

This daunting series of steps, once performed, leads to an accepted name. The advantage of the internationally agreed on Codes is that whoever follows the steps faithfully will come to the same answer regarding the name to be used in a particular

taxonomy. That name will remain stable unless new nomenclatural or taxonomic information comes to light (see Why Names Change) and the taxonomy is changed.

Faced with such complexity, users of names wishing to check the currently accepted name for an organism need shortcuts. Recent world monographs and checklists are the first port of call, and then any regional or national treatments. If these are not available, and there is no taxonomist specializing in the group that can be consulted, it will be necessary to check the main indices of names and supporting bibliographic databases or abstract publications (e.g., Biological Abstracts, Kew Record, or Bibliography of Systematic Mycology). The possibilities for the online checking of names is improving year on year (see Indices of Names). However, that will not obviate the need for checking, which should be viewed as a necessary evil in all biodiversity inventory work and in biological papers in general. If research is published using an unfamiliar obsolete name, it may never be retrieved from the hundreds of thousands of scientific articles that appear each year, or linked to other pertinent information.

Indices of Names

There is a series of major online and printed reference works of the scientific names of organisms that focus on different major groups and that vary with respect to the information captured. There are too many to list here, but especially important are: AlgaeBase, FishBase, Index Kewensis, Index Fungorum, Integrated Taxonomic Information System, International Plant Names Index, Zoological Record, and the Approved Lists of Bacterial Names.

Major progress has been made toward a one-stop shop for information on names of all kinds of organisms in the *Catalogue of Life*, a collaborative project that brings together data on names from 77 global species databases: the 2010 annual checklist includes data on the names of a staggering 1.25 million currently accepted species.

Glossary

Allopatric Populations, species, or taxa occupying different and disjunct geographical areas.

Ecotone The boundary or transitional zone between adjacent ecological communities or biomes.

Epistasis The interaction of non-allelic genes in which one gene (epistatic gene) masks the expression of another gene at a different locus.

Genetic drift The occurrence of random changes in the gene frequencies of small isolated populations not due to selection, mutation, or immigration.

Isolating mechanisms Any intrinsic or extrinsic mechanism or barrier that inhibits the free exchange of genes between populations.

Pleiotropic gene A gene that has more than one independent phenotypic effect.

Polyloid Having more than one set of homologous chromosomes.

Sister species A pair of species that have arisen from a single speciation event; each is the other's closest relative.

Sympatric Populations, species, or taxa that occur together in the same geographical area within the dispersal range of one another.

Speciation and Species

Speciation

The ultimate source of the earth's biodiversity is speciation, a process that occurs when gene flow is reduced sufficiently between sister populations to allow each to become irrevocably committed to different evolutionary lineages. Speciation results in the splitting of a lineage into two or more species (cladogenesis). However, when a species is transformed over time (anagenesis) by the acquisition of phenotypic and genetic modification, there is no increase in the number of species and thus no speciation event (Figure 1a).

The Species Problem

Although the end product of speciation seems clear, defining when and under what conditions two populations become irrevocably committed to different evolutionary lineages has proved to be difficult and controversial. A frequently invoked species definition is the biological species concept (BSC) of Mayr (1942), who proposed that "species are groups of actually or potentially interbreeding natural populations that are reproductively isolated from other such groups" (p. 120).

However, the BSC and its later modifications have several limitations. It can be applied objectively only to sexually reproducing taxa and to natural populations that are sympatric (i.e., those that occur in the same geographic area) where they have the opportunity to interbreed. Asexually reproducing taxa and fossils must be treated subjectively. A more serious limitation of the BSC is that sympatric taxa that maintain distinct phenotypic and genotypic differences, but sustain some gene flow through interbreeding with close relatives, are generally not recognized as species. Recent molecular studies on closely related sympatric animal and plant taxa recognized as distinct,

closely related sister species (the products of one speciation event) reveal that gene flow between them may still occur (Feder *et al.*, 1995; Taylor *et al.*, 1997). Such neospecies have acquired sufficient genetically based differences to maintain independent genotypes and distinct phenotypes but are still capable of sustaining some gene flow as they diverge. Several other species concepts have been proposed (Futuyma, 1998), but all suffer from problems of circularity, inconsistencies, and untestable qualities.

For this reason, the genetic-based species concept of Mallet (1995) provides a useful, less assumption-laden, operational species definition for identifying sister species. Mallet proposed that sister species be recognized only when they maintain distinctly different sympatric genotypic clusters. Defining a species based on genotypic clusters represents the level of differentiation most interesting to those studying speciation. Generally, sympatric sister taxa that maintain distinct genotypic clusters exploit different habitats or hosts. The wide use of modern DNA analysis in evolutionary studies makes this a useful approach particularly when coupled with sound biological studies. However, as with the BSC, using genotypic clusters to determine the biological status of geographically isolated sister populations without a "test of sympatry" is still a subjective although somewhat more quantitative call.

Reproductive Barriers to Gene Flow and the Evolution of Mate Recognition Systems

Reproductive Barriers

The free exchange of genes between populations adapting to different niches inhibits the evolution of independent genetic systems. As soon as adaptive gene combinations are formed, they are broken up by recombination through interbreeding. There are several biologically based reproductive barriers or

Figure 1 Major modes of speciation. See text for details on the processes involved in divergence and speciation.

“isolating mechanisms” that evolve during the course of speciation which limit gene flow between sister species (Table 1). These biological barriers constitute components of a mate recognition system that promotes assortative mating between individuals adapted or adapting to shared environmental and reproductive conditions.

Two Modes of Speciation

There are two primary modes of speciation recognized by most evolutionary biologists (Table 2). Allopatric (geographic) speciation occurs when sister populations are isolated for a period by a physical barrier such as a mountain range or an expanse of uninhabitable terrain or water. In the absence of gene flow, such isolated populations inevitably accumulate unique mutations and, over time, may diverge genetically by genetic drift and in response to divergent selection pressures. If sufficient genetic divergence occurs during isolation to establish and maintain distinct genotypic clusters, particularly when their ranges later overlap, then the taxa are regarded as species.

Non-allopatric (ecological) speciation occurs in the absence of physical barriers to gene flow when sister populations

diverge genetically and become ecologically and reproductively isolated as they adapt to different habitats. New sister species thus evolve within the dispersal range of the offspring from a single deme. Several different patterns of geographic and ecological speciation are recognized based on the factors involved in promoting their divergence, such as population structure, habitat specialization, hybridization, and polyploidy.

Geography, Geographic Races, and Allopatric Speciation

The process of geographic speciation (often referred to as allopatric speciation) may happen in two ways. Dichopatric or vicariant speciation (Figure 1b) occurs when a widespread species becomes geographically divided into two or more large subpopulations by an insurmountable or impassable barrier. A second mode of geographic speciation, usually called peripatric or founder event speciation (Figure 1c), occurs when a geographically isolated population is established by a single fertilized female or a very small number of founding individuals.

However, determining the actual biological status of sister taxa that have arisen in isolation following either a vicariant or a founder event is difficult and controversial. Species can be

Table 1 Classification of reproductive isolating mechanisms

Prezygotic isolating mechanisms: mechanisms that prevent interspecific mating
Temporal isolation (potential mates have overlapping ranges but reproduction occurs at different times)
Habitat isolation (potential mates have overlapping ranges but reproduction occurs in different habitats)
Ethological isolation (potential mates meet but do not mate)
Mechanical isolation (potential mates attempt to copulate but no sperm is transferred)
Mechanism that prevents fertilization
Gametic mortality (sperm is transferred but egg is not fertilized)
Gametic incompatibility (gametes meet but fertilization is not completed)
Postzygotic isolating mechanisms: mechanisms that prevent the development of interspecific hybrids
Zygote mortality (eggs fertilized but zygote dies)
Hybrid inviability (zygote produces F ₁ hybrid of reduced viability)
Hybrid sterility (F ₁ hybrid zygote is fully viable but partially or completely sterile or produces deficient F ₂ hybrid)
Coevolutionary or cytoplasmic interactions (individuals from a population infected by an endoparasite or with a particular cytoplasmic element are fertile with each other, but fertility and/or viability break down when matings occur between infected and uninfected individuals)

Table 2 Classification of modes of speciation

Allopatric speciation
Dichopatric speciation (vicariant division of wide-ranging species by an extrinsic barrier or extinction of intervening populations)
Peripatric speciation (by evolution in a very small isolated colony)
Nonallopatric speciation
Parapatric speciation
Sympatric speciation
Autopolyploid speciation

Allopolyploid speciation
Direct and reticulate alloigenous speciation
Symbiont-induced speciation

recognized when artificial hybridization of allopatric taxa in the laboratory reveals post-mating reproductive isolation. If no post-mating incompatibility is noted and mating occurs, then it is necessary to determine if there are factors important in pre-mating isolation not provided in the laboratory environment of the tests. Whether or not such populations are species or geographic races may require an unequivocal “test of sympatry” in which the two taxa coexist without fusing. Only when previously isolated taxa have the opportunity to interbreed under natural field conditions can the species status of closely related taxa lacking post-mating reproductive isolation be confirmed. If they maintain distinct sympatric genotypic clusters, they should be recognized as distinct species. Because such tests cannot often be performed, deciding on whether isolated taxa represent species or geographic races (i.e., subspecies) is a subjective decision. However, it should be stressed that when two taxa overlap naturally (i.e., are parapatric) and do not interbreed, this does not necessarily mean that they speciated sympatrically. This is because it is often impossible to establish if the overlap represents a case of

secondary contact following allopatric speciation or if the taxa evolved as the result of non-allopatric divergence.

Dichopatric Speciation

When populations of geographically isolated sister taxa remain large during and following geographic subdivision, they will slowly diverge genetically by genetic drift and as they adapt to local conditions in isolation. Over time, they may accumulate sufficient genetic differences to cause negative pleiotropic gene interaction and hybrid incompatibility among genes responsible for proper mate recognition and genome integration. Reproductive isolation therefore occurs by chance as the by-product of genetic divergence in isolation rather than the outcome of natural selection acting directly to promote reproductive isolation.

Dichopatric race Formation and Speciation in Salamanders

The long-term study of evolution in the plethodontid salamander genus *Ensatina* by David Wake and colleagues (Wake and Schneider, 1998; Wake, 1997) provides an excellent example of dichopatric speciation and incipient species formation. The *Ensatina eschscholtzii* complex represents an ancient lineage that has undergone several instances of range contraction, isolation, and expansion and divergence of populations along broad ecological gradients. It is composed of seven contiguous subspecies wrapped in ring-like fashion around the Central San Joaquin Valley of California (Figure 2). Historically, populations of *Ensatina* slowly differentiated into highly distinct forms from the northern subspecies *E. e. oregonensis* in color and pattern as they expanded southward. Blotched forms occur in the Sierra Nevada and mountains of southern California, whereas unblotched forms are found in the coastal and northern region of their range. The animals, which are long-lived (10–15 years) and take 4 years to mature, are sedentary and disperse only short distances (home range 10–20 m).

Hybridization and intergradation occur between adjacent subspecies to varying degrees in all except one contact zone. The exception occurs in the Cuyamaca Mountains of San Diego County, in which *E. e. eschscholtzii* and *E. e. klauberi*

Figure 2 Geographic distribution of taxa in the salamander *Ensatina* complex based on molecular markers rather than morphological traits. Modified with permission from Wake DB (1997) Incipient species formation in salamanders of the *Ensatina* complex. *Proc. Natl. Acad. Sci. USA* 94: 7761–7767, and Futuyma DJ (1998) *Evolutionary Biology*. Sunderland, MA: Sinauer.

overlap but rarely interbreed in sympatry and are regarded by some biologists as distinct species. In other areas, the complex includes many geographically and genetically distinct entities, some of which are near the species level of differentiation.

A limited narrow secondary hybrid zone also occurs in Calaveras County between the upland *E. e. platensis* and a coastal, lowland subspecies, *E. e. xanthoptica* that established an outpost in the Sierran foothills sometime in the past. *Ensatina e. platensis* lives in the cool and moist, closed canopy forest at higher elevation than those of *E. e. xanthoptica*, which

prefers warmer and drier lower elevations. Hybridization between the pure subspecies is rare, with most hybrids representing progeny from backcrosses or from crosses between hybrid individuals. Hybrid individuals appear to be at a selective disadvantage and thus subject to strong negative selection. They have reduced success in competing for preferred habitats and mates and seem to be more prone to predation. Because little or no gene flow occurs across the narrow hybrid zone, the coastal and Sierra taxons behave as incipient species or taxa in the final stages of speciation. Four other hybrid

zones in central California involving *E. e. xanthoptica* have been characterized in detail. The *Ensatina* complex presents a full array of differentiation from geographically variable populations or races to well-marked species. It provides an excellent example of how speciation has progressed slowly by adaptive divergence and stochastic processes during periods of geographic isolation.

Peripatric Speciation and the Founder Effect Principle

There are several examples in which species appear to have evolved in small, isolated populations at the periphery of the range of a sister species. Unlike the slow rate of evolution in dichopatric speciation, peripatric speciation is postulated to take a relatively short time. How and how often this divergence occurs is controversial (Barton, 1996; Hollocher, 1996).

Three models, each based on a founder event in which a population is established by only a few individuals, have been proposed to account for the rapid evolution of species observed on islands and elsewhere (Figure 1c). The founder effect principle was developed by Mayr (1954). It is based on the assumption that reproductive isolation from the parent species can evolve rapidly in a population established by a very small number of founding individuals (i.e., 2–10). He postulated that in such populations a genetic revolution could take place as a by-product of inbreeding, selection, drift, and genome reorganization. While the population is small, these genetic changes may promote substantial morphological and ecological shifts.

A modification of the founder effect principle was proposed by Carson (1975). In his founder-flush model of speciation, isolated populations undergo a series of population expansions and drastic contractions to a very small number of individuals. Carson believes that founder-flush speciation can occur only in certain cross fertilizing diploid organisms with “open” genetic systems. The genome in such organisms represents a clique of harmoniously collaborating or coadapted genes united by strong epistatic interactions. Their genomes also have abundant pleiotropic interacting genetic polymorphisms and share a high recombination index. Carson hypothesized that these attributes provide great genetic flexibility that predisposes such organisms to speciate by the founder-flush process.

In Carson’s view, the drastic events required to reorganize the original genetic system and restore new balances that are incompatible with ancestors are accomplished during cycles of the founder-flush process. Selection, which is relaxed during the flush phase of population expansion, is greatly intensified as the population crashes. Repeated disorganization and reconstitution of the genome results in the rapid evolution of reproductive isolation.

Templeton (1980) proposed a third modification of founder-induced speciation that involves a genetic transilience (Carson and Templeton, 1984). It is similar to Carson’s founder-flush speciation but requires changes in only one or a few segregating units, commonly with epistatic modifiers responsible for reproductive isolation that occurs when a population rapidly passes through an extremely unstable intermediate genetic state. As in the case of the founder-flush model, a genetic transilience involves strong inbreeding and

large variance in population size. The critical trigger that initiates a transilience requires a reweighting of fitness components owing to drift-induced shifts in allele frequencies at one or more major loci that have pleiotropic effects on reproductive isolation.

It seems clear that speciation may occur rapidly following the geographic isolation of a small population. It is not clear, however, whether speciation results from a founder-flush or transilience process or solely from natural selection in response to factors such as runaway sexual selection or rapid adaptation to divergent ecological and reproductive conditions. Because conditions required for stochastic transitions are severe and well documented cases are lacking in which drastic genetic changes caused by founder effects result in speciation, it appears that the process of speciation in small, peripheral populations is the same as that which occurs in dichopatric speciation. Although certain kinds of epistasis can promote strong reproductive isolation, divergence occurs by selection and not random genetic drift (Barton, 1996).

Ecology, Ecological Races, and Nonallopatric (Ecological) Speciation

Reproductive isolation between sister populations in cases of allopatric speciation arises as a by-product of genetic changes that originate and accumulate independently in each population during periods of geographic isolation. Speciation may or may not be accompanied by an ecological transformation. In contrast, nonallopatric or ecological speciation inevitably involves a shift to a new niche at the time of speciation, and adaptation to different habitats is the driving force initiating and sustaining genetic divergence (Figures 1d–1f). Divergent selection on existing genetic variation results in the evolution of reproductive isolation as different suites of genetic variants are favored in each habitat. The emergence of reproductive isolation is also facilitated when mating occurs within a preferred habitat or if mate preference that is based on a phenotypic variant of a sexually selected trait becomes associated with a preferred habitat (Johnson *et al.*, 1996).

A misconception concerning nonallopatric speciation is that it requires a process called reinforcement, which involves the divergence of the mate recognition system between populations during the speciation process as an outcome of selection against hybrids (Butlin, 1987). Because theoretical models suggest that recombination will not allow reproductive reinforcement to develop, critics have argued that parapatric and sympatric speciation are unlikely to occur in nature. These models, however, fail to factor in the role of habitat preference and specialization in speciation and the effects of ecological divergence, which always accompanies sympatric speciation. When habitat choice is taken into consideration, conditions for sympatric speciation are greatly relaxed and its occurrence is probable (Johnson *et al.*, 1996).

Three modes of nonallopatric speciation are generally recognized in sexually reproducing organisms. Parapatric speciation (Figure 1d) takes place when sister species evolve while adapting to contiguous but spatially segregated habitats or ecotones across a narrow contact zone (Bush, 1994). Sympatric speciation (Figure 1e) occurs in the absence of

geographic segregation when sister species evolve within the dispersal range of the offspring of a single deme. During the course of sympatric speciation, the probability of mating between two individuals depends on their genotypes, and divergence occurs between populations adapting to alternate habitats within the “cruising range” of each other. Parapatric and sympatric speciation actually represent extremes of a continuum in the pattern and extent of habitat and geographic-imposed spatial segregation and gene flow reduction that occurs during nonallopatric divergence. Hybridization (Figure 1f) is a third mode of nonallopatric speciation. New species rapidly evolve from a mating between individuals of two closely related species by a variety of different processes. It is a frequent mode of speciation in plants but appears to be rare in animals.

Parapatric Speciation

This mode of speciation occurs when sister species evolve while adapting to contiguous habitats (or ecotones along a zone of contact). Examples from nature involve situations in which individuals from a species adapted to one habitat invade and colonize an adjacent habitat. Individuals bearing novel genetic recombinants capable of exploiting and reproducing in the new habitat are the first to invade and colonize the narrow zone where the two habitats meet. As adaptation proceeds, the new colony expands throughout the range of the new habitat. Only along the adjoining borders between the original and new habitat is gene exchange possible between the two populations. As the new population adapts to conditions imposed by the new habitat, divergent selection promotes the evolution of reproductive isolation and eventually parapatric species.

Parapatric Speciation in *Mimulus*

An example of rapid parapatric adaptation and speciation of a plant to a newly established vacant niche is that of the monkey flower *Mimulus cupriphilis* in California (Macnair and Gardner, 1998). This species grows only on relatively dry and toxic mine tailings of two small copper mines in California. It grows in close proximity and is recently derived from the widespread hydrophylic *M. guttatus*.

The two species differ in many ways. *Mimulus cupriphilis*, an obligate annual, flowers earlier and produces many small flowers that differ in shape and color from those of *M. guttatus*. *Mimulus cupriphilis* also has higher fitness on the dry tailings of the copper mines and flowers early when pollinators are rare. Because it is self-fertilizing, it is reproductively isolated from the outcrosser *M. guttatus*, which blooms later when its larger flowers are fertilized by bumblebees. Genetic studies have revealed that the species differ in a few major genes controlling flowering time, flower size, corolla spot number, and general size. Because all the genetic systems are recessive with the exception of flowering time, recessive alleles would be spread by natural selection in the original outbreeding parent species. In inbreeders, there is no difference between dominant and recessive alleles.

Mimulus cupriphilis has evolved recently since the copper mines are less than 150 years old. The shift to the new soils created by the mines involved the development of a copper-tolerant ecotype with a primary semidominant adaptive

mutation that shifted flowering time earlier in the plants growing in dry habitats. In the absence of pollinators early in the season, selection favored alleles for self-fertilization. This was accomplished by flower size reduction that brought the stigma and anthers in close proximity. Reduction in size of corolla and associated structures may have also freed up resources for seed production. The result is a new selfing species that has evolved locally in a very short time and that is well adapted to the unique conditions of the mine tailing fields.

There is no evidence of a genetic revolution or reduction in genetic diversity in the new species and F_2 progeny. Nor is there evidence of significant breakdown in so-called gene complexes or major epistatic interactions. Therefore, it is concluded that speciation has been achieved by new selection pressures on normal *M. guttatus* as it colonized a new and unusual habitat. Major genes of large effect that play important roles in reproductive isolation have also been demonstrated in other sister species of *Mimulus* species (Bradshaw *et al.*, 1995). In such cases, new species have the potential to appear nearly full-blown in relatively few evolutionary steps because of changes in a few essential genes.

Sympatric Speciation

It is now apparent that sympatric speciation, once thought to be rare in animals and plants, occurs more frequently than previously realized. Because two closely related sympatric sister species cannot share the same resources, nonallopatric speciation is inevitably accompanied by the shift and exploitation of a new habitat by the daughter species. Such habitat or resource shifts reduce competition between sister species. It is for this reason that sympatric speciation is often referred to as ecological speciation.

Sympatric Speciation in Cichlid Fish

The important role of ecology in sympatric speciation is exemplified by the study of Schliewen *et al.* (1994). In a molecular phylogenetic study they discovered that two endemic cichlid fish species flocks (9 and 11 species) in two small, ecologically monotonous volcanic lakes (4.15 and 0.6 km²) in Cameroon speciated sympatrically. Because each crater is isolated from rivers and lacks internal structure, past lake levels are not responsible for physically isolating sister populations during speciation. Field observations, stomach content analyses, and the presence of specialized morphological features related to feeding confirm that the species within each lake have different benthic or pelagic trophic and reproductive ecologies. Although all species nest on the bottom and are capable of encountering one another at moderately high frequencies along ecotones, no hybrids are found because the species mate assortatively and do not interbreed.

Phylogenetic trees were constructed based on an analyses of a 340-base pair fragment of mtDNA cytochrome b and an additional 350 base pairs from the rapidly evolving mitochondrial control region for all 20 species and all tilapia species in neighboring river systems and lakes. This analysis confirmed that the lake species are monophyletic with respect to the river species, i.e., each flock evolved within each lake after a single colonization event.

Sympatric Host Race Formation and Speciation in Rhagoletis Fruit Flies

The importance of habitat and resource shifts in the non-allopatric speciation process is exemplified in the case of recent host race formation and speciation in the tephritid fruit fly genus *Rhagoletis* (Bush and Smith, 1998; Feder, 1998). As in other phytophagous and parasitic insects, mating in these flies occurs on the host plant, primarily on the host fruit in which eggs are deposited and larvae develop. *Rhagoletis pomonella*, whose native hosts are fruits of several hawthorn (*Crataegus*) species, colonized apples in approximately 1860, more than 200 years after this fruit tree was introduced to North America by Europeans. Early infestations on apples were restricted to a small area of the Hudson River valley in southern New York where hawthorn is common. The apple flies later spread over the entire northeastern United States and southeastern Canada, where it became a major pest. In a brief span of 150 years, the apple and hawthorn populations diverged in several genetically based traits, such as eclosion time of the adult in summer, and host recognition and acceptance. In addition, strong frequency differences in alleles at several loci coding for proteins are maintained by strong selection and greatly reduced gene flow between the races. The apple and hawthorn races now behave as semispecies or species. All seven members of the *R. pomonella* species group are sympatric in eastern North America and speciation in this species group has always been accompanied by a shift to a new host plant family or genus.

Other Modes of Nonallopatric Speciation

Spontaneous Thelytokous Speciation

This mode of sympatric speciation occurs when a unisexually reproducing taxa arises spontaneously from an unfertilized egg of a diploid bisexual species. Subsequent reproduction in taxa originating in this way produces only females from unfertilized eggs. Several good examples are provided by White (1978).

Autopolyploid Speciation

Occasionally, polyploidization of a diploid species may occur spontaneously in one or more individuals. Because autopolyploid individuals have three or more chromosome sets, each chromosome has more than one homologous pairing partner. During meiosis, multivalents are produced leading to unbalanced gametes and zygotes, sterility, and other problems. Only rarely does autopolyploidy result in the origin of new species, such as in the common potato (*Solanum tuberosum*) and its relatives (Grant, 1981). These usually originate from crosses between races whose chromosomes differ only slightly.

Speciation by Interspecific Hybridization

A new species can arise two ways by interspecific hybridization (Figure 1f). Homoploid hybrid speciation results in a diploid-derived species, whereas polyploid hybrid speciation produces a species that combines a complete set of chromosomes from each hybridizing parental species. Hybrid species occupy habitats different from those of the parental species, thus

reducing competition and the level of gene flow between them. Hybrid speciation, which is far more common in plants than in animals, can occur in at least four ways.

Introgressive Hybrid Speciation

Individual gene exchange among closely related species provides recombinant offspring that shift to and exploit a new habitat not utilized by either parental species. The hybrid species may be interfertile with one or both parental species, but it is reproductively isolated from them by premating barriers to gene flow. This mode of speciation has been reported in several plant species (Grant, 1981), but confirmation of this mode of speciation remains controversial and requires definitive experimental and analytical studies.

Recombinational Hybrid Speciation

A far more common mode of hybrid speciation involves the formation and establishment in the progeny of a chromosomally sterile or semisterile species hybrid of a new, structurally homozygous recombination type. Individuals are fertile within the line but isolated from other lines and from the parental species by a chromosomal sterility barrier. It is most likely to occur when the hybrid interface is long and the organisms involved are predominantly selfing, relatively fertile, and possess few structural chromosome differences between the parental species.

Hybrid Speciation in Wild Sunflowers

A molecular study of hybrid speciation in the wild sunflowers *Helianthus* by Rieseberg *et al.* (1995) revealed that F_1 hybrids of *H. annuus* and *H. petiolaris* are semisterile with pollen viabilities less than 10% and seed set less than 1%. F_2 pollen viability is highly variable, ranging from 13 to 97%. The two species are distinguished by several morphological and chromosomal features, and based on chloroplast DNA and nuclear ribosomal DNA variation they occur in divergent clades. Although the species are sympatric throughout much of the western United States, they have different ecological requirements. *Helianthus annuus* is restricted to heavy, clay soils, whereas *H. petiolaris* predominantly inhabits dry, sandy soils.

Helianthus anomalus is a rare endemic to xeric habitats in northern Arizona and southern Utah. It is well within range of parental species and is a recombinational hybrid resulting from a cross between *H. annuus* and *H. petiolaris*. The F_1 hybrids with parental species are partially sterile because chromosomal structural differences enhance reproductive isolation. A preliminary survey of 126 loci in natural populations of the parental species indicated that *H. anomalus* has loci derived from both *H. annuus* and *H. petiolaris*. Some blocks of markers, possibly protected from recombination, are transmitted intact.

Helianthus anomalus combines rDNA repeat units and allozymes of *H. annuus* and *H. petiolaris* as predicted for diploid hybrid species, although individuals possess chDNA haplotypes of *H. annuus* and *H. petiolaris* rather than a unique haplotype. Genetic linkage maps generated for all three species using random amplified polymorphic DNA markers reveal loci distributed onto 17 linkage groups corresponding to the haploid chromosome number of the three species. Although levels of polymorphisms vary from 212 in *H. annuus* to 400 in

H. petiolaris, map density is similar among species. By comparing genomic location and linear order of homologous markers, chromosomal structural relationships were inferred among the three species.

Even though 6 linkage groups showed no changes in all three species, the remaining 11 linkages were not conserved in gene order. The parental species differ from *H. anomalus* by at least 10 separate structural rearrangements, 3 inversions and a minimum of 7 inter-chromosomal translocations. The genome of *H. anomalus* is thus extensively rearranged relative to its parents. All 7 novel rearrangements in *H. anomalus* involve linkage groups that are structurally divergent in parental species, suggesting that structural differences may induce additional chromosomal rearrangements upon recombination.

Allopolyploid (Amphiploid) Speciation

Interspecific hybridization can also result in combining two or more complete chromosome sets. F_1 hybrids produced between two established related species are often sterile because chromosomes lack sufficient homology to pair well at meiosis. Fertility is restored if hybrids persist long enough by asexual reproduction until somatic doubling of the chromosomes can occur in a flower, or until there is a rare union between two unreduced gametes. A new sexually reproducing species is

then established that is “instantaneously” isolated from both parental species (Grant, 1981).

Allopolyploid Speciation in *Spartina Anglica*

The recent natural rapid evolution of the amphiploid perennial salt marsh grass, *Spartina anglica*, provides an example of allopolyploid speciation (Raybould *et al.*, 1991). This species originated on the south coast of England at the end of the nineteenth century. It arose as a result of chromosome doubling in *S. x townsendii*, a hybrid between the native British *S. maritima* and the North American *S. alterniflora*, introduced by shipping (Figure 3). *Spartina anglica* is now widespread along the English coast and is highly successful.

Although more than half of all plant species are directly or indirectly the by-products of allopolyploid speciation, allopolyploid speciation is relatively rare in animals (White, 1978).

Direct and Reticulate Alloigenous Speciation

There are two modes of alloigenous speciation (i.e., combining the genomes of two distinct species). In the case of direct alloigenous speciation, hybridization between two bisexual, closely related species combines the genomes of two distinct parental species giving rise to a new, unisexual species (Bullini, 1994). The hybridization event produces either an allodiploid or an allopolyploid unisexual species that acquires clonal (parthenogenesis) or hemiclinal (hybridogenesis; i.e., it must mate with males of a bisexual parental species) modes of reproduction. In most such clonal and hemiclinal organisms, the heterozygous genetic structure of the parental species is retained.

In the case of reticulate alloigenous speciation, individuals of unisexual hybrid taxon hybridize with a bisexual relative giving rise to new, unisexual species, often with a higher ploidy level than that of the parental species (Bullini, 1994). Most have highly heterozygous genomes that display heterosis. Clones produced by direct and indirect alloigenous speciation exhibit heterosis and demographic advantage over both parental species and individuals.

Summary

After 140 years of speciation research, it is now clear that animal and plant species can originate in a variety of ways. Rapid autopolyploid speciation is common in plants and accounts for many plant species. In animals, this mode of speciation is relatively rare. Dichopatric speciation gives rise to many, possibly the majority, of the species in some animal groups such as the land vertebrates. In fish, both allopatric and nonallopatric speciation have been reported. The majority of living organisms, however, are insects. Some authorities estimate there are as many as 30–40 million species, and all agree that there are more than 10 million. Approximately 70–75% are highly specialized parasites that feed in or on plant and animal tissue. Although many of these insects probably originated by nonallopatric speciation, it is not clear what percentage have done so. The same is true for the many mites and nematode species that also may number in

Figure 3 The origin of the allopolyploid marsh grass species *Spartina anglica* (AABB) that resulted from hybridization between *S. maritima* (AA) and *S. alterniflora* (BB). Each letter in parentheses represents a haploid genome. The sterile hybrid, *S. x townsendii* (AB), reproduced vegetatively until the genomes of individual plants doubled by autopolyploidy. This results in the establishment of a new fertile sexually reproducing tetraploid species, *S. anglica*, with a full complement of chromosomes from *S. maritima* and *S. alterniflora* (AABB) that can produce normal gametes (ab).

the millions. Because the mode of speciation in only an extremely small number of animal and plant species has been established, it is impossible to estimate how often each mode of speciation occurs in any particular group of organisms. Such estimates must await research on a great many more taxa.

Glossary

Coadapted gene complexes Genes that have been selected to work in a coordinated fashion to confer high fitness.

Epistasis An interaction between different alleles at two or more loci such that the phenotype differs from what would be expected if each locus acted independently.

Fitness The average number of offspring produced by individuals with a certain genotype relative to the number produced by individuals with other genotypes as a result of differences in survival and reproductive success.

Gene pool The collective set of genes in a population at a particular time.

Heterogamety Having two different sex chromosomes.

Hybrid inviability The phenomenon whereby one or both sexes of progeny produced in crosses between two different species is unable to survive.

Hybrid sterility The phenomenon whereby one or both sexes of progeny produced in crosses between two different species are able to survive, yet are unable to reproduce.

Pleiotropy One gene affects more than one trait.

Reproductive isolation Intrinsic barriers to the production of offspring.

Introduction

Speciation is the process by which new species are formed. Thus, its central importance to the study of evolution and issues of biodiversity cannot be overstated. The seemingly simple definition of speciation as the origin of species belies the fact that the actual process of speciation is almost as complex and varied as the diversity of life itself. No one mechanism of speciation is sufficient to describe the origination of all the diversity we see in the world and more often than not several speciation mechanisms come into play simultaneously in the formation of a single new species. The study of speciation attempts to analyze these competing mechanisms to determine the relative importance of different evolutionary processes promoting species divergence under particular circumstances. By looking for recurring patterns across a wide spectrum of individual case studies, we are devising models that help explain speciation more generally. This knowledge then serves as a framework for making policy decisions regarding the preservation of biodiversity, for the ultimate goal of conservation biology is not just to preserve current species, but also to preserve the natural processes that help generate new ones.

Theoretical Considerations

Although speciation has been studied intensively for more than 150 years, only recently have we begun to develop a clearer understanding of the general patterns of genetic change that occur during the process. This type of knowledge is absolutely essential for describing speciation using a population genetic framework. A key aspect of all population genetic models of speciation is the assumptions made about the underlying genetic architecture – the number and types of genes and their interactions – of traits that have changed during speciation. Differing underlying genetic architecture of traits can influence directly how they respond during speciation even when the same evolutionary processes are known to be at play (e.g., see Rettelbach *et al.*, 2011; Nosil and

Schluter, 2011). Therefore, examination of the genetic architecture of species differences is one fruitful avenue for gaining insights into the evolutionary processes involved in speciation.

Equally important to theories of speciation is determining which traits are most influential for promoting species divergence. We recognize species because they are different from one another, be it morphologically, behaviorally, or reproductively. In all cases, a sequence of events has led to the eventual fixation of these observed differences. Knowing whether certain traits are more prone to change than others during speciation or whether certain traits have a larger impact either on past or future patterns of divergence directly informs our models of speciation. This knowledge improves our ability to target groups of organisms at the nascent stage of divergence and to focus our attention on specific traits for future studies of speciation that will allow general patterns to emerge.

Defining Species

Why is There More Than One Definition of Species?

One would think that by now evolutionary biologists would agree on what constitutes a species. However, it turns out that species concepts are almost as varied as the types of researchers that work on the question. To date there is no single, universally accepted definition of a species, although certain frameworks for thinking about species have come in and out of favor over the years (Howard and Berlocher, 1998; Coyne and Orr, 2004; Wilkins, 2009). Most definitions of species serve a useful research purpose and are a function of the types of questions that are being addressed (e.g., whether species designations should serve a strictly taxonomic purpose as in systematics or represent the active evolutionary unit of diversification as in population genetics). This is not to imply that the definition of species is purely a semantic issue, but rather that the diversity of definitions reflects very different perspectives as to what factors should be emphasized in

describing species. Beyond these purely theoretical issues, species concepts have an additional problem of not always being easy to apply in real-life situations.

As a result of these conflicting purposes of species concepts, every subdiscipline within speciation research has formulated its own particular species concept. However, the problems surrounding species definitions are more fundamental than simple differences in perspective. There is an inherent problem of trying to categorize groups of organisms that are undergoing a continual process of change. Speciation is a process, not an instantaneous event. It is also not caused by a single unified mechanism, but by a collection of different mechanisms of divergence affecting different traits at potentially different rates. The formation of natural groups does eventually result from the ongoing action of each of these processes of divergence and at some point in time these natural groups can and should be delineated as separate species. However, because of the fluidity of the process, the boundaries that circumscribe these natural groups are often at best blurry given the fact that each underlying mechanism of divergence can potentially delineate a separate natural group. In some instances, this creates no problem and these different boundaries will actually coincide with each other. In these cases, several different species concepts will correspondingly give the same species designations. In other instances, these boundaries may not correspond well at all. Hence, depending on which process is being emphasized, the actual definition of a particular species may also vary in these circumstances. In most cases, conflicting species boundaries are not so much a problem of the competing species definitions as they are a reflection of the complicated nature of the underlying biological process that governs speciation. For a population geneticist interested in the process of speciation, it is those cases where the boundaries of divergence based on different criteria do not correspond well that often prove to be most interesting to study.

Most Commonly Used Species Concepts

Because of space constraints, a thorough critique of competing species concepts is beyond the scope of this article (see the chapters by De Queiroz, Harrison, Shaw, and Templeton in Howard and Berlocher, 1998; for a more philosophical and historical treatise see Wilkins, 2009). However, a general overview of the most commonly used species concepts will be presented here, paying particular attention to how each concept relates to the elucidation of underlying speciation processes.

Morphological and Phenetic Species Concepts

Intuitively, using morphological criteria to get a first approximation of species boundaries works rather well. Different groups of organisms look different from each other. This simple “morphological species concept” was used by the early naturalists of the eighteenth and nineteenth centuries and is still often used today by field biologists and paleontologists. Most evolutionary biologists also use this concept as a starting point to which other criteria are then later added (the fact that species appear morphologically distinct is usually taken for granted by most practicing evolutionary biologists). The

“phenetic species concept” embellishes on this first approximation by incorporating specific morphometric analyses to describe explicitly the phenotypic groupings. From a functional point of view, groups of organisms that are morphologically distinct most likely represent different groups genetically as well.

Using morphological criteria alone, however, carries with it the risk of categorizing groups of organisms as the same species when indeed there are reproductive barriers between them (as is the case for cryptic species, which are morphologically identical but nevertheless represent distinctly different gene pools) or categorizing groups of organisms as separate species when in fact the difference is not genetically based, but solely a phenotypic response to varying ecological conditions (such as the case for some plants that can change the morphology of their leaves in response to varying light levels). In addition, the categorization of species based solely on morphological criteria without the incorporation of an explicit evolutionary framework is generally unsatisfactory to the majority of people working in the field of speciation.

The Genotypic Species Cluster Definition

An improvement over most morphological approaches to defining species has been proposed by Mallet (1995) using genetic criteria to cluster groups of organisms rather than strictly morphological traits (termed the “genotypic species cluster” definition). In this case species are defined as genetically distinguishable groups of individuals that exhibit few or no intermediate genotypes (both for single and multiple loci) when in contact. This is clearly an advantage over strict morphological criteria because it gets right to the heart of speciation – genetic differentiation. It is also very satisfying as an operational definition of species groups, because genetic clustering is easily diagnosable for all taxa, whether sexual or asexual. However, this definition is only easily applicable to the situation where species are in direct contact with each other and cannot be generally applied. More importantly, it is still a phenetic approach to species definitions and lacks any inherent evolutionary framework for the interpretation of species groups from a mechanistic point of view.

The Biological and Recognition Species Concepts

Until recently, the most enduring species concept has been the “biological species concept,” first outlined in detail by Dobzhansky (1937) and subsequently popularized by Mayr (reviewed in Mayr, 1982). The concept defines species as interbreeding groups of organisms that are reproductively isolated from other groups. In other words, species are groups of organisms that share a common gene pool. Speciation, under this concept, is the development of a biological barrier to gene flow and the subsequent differentiation of the two resulting gene pools. Biological barriers to gene flow were termed isolating mechanisms and covered the full gamut from prezygotic barriers (including ecological or habitat isolation, seasonal or temporal isolation, sexual or ethological isolation, mechanical or physiological barriers to mating, isolation by different pollinators, and gametic isolation blocking fertilization) to postzygotic barriers (including hybrid sterility, hybrid inviability, and other forms of reduced fitness in progeny

resulting from crosses between differentiated populations). The biological species concept is firmly rooted in speciation processes and encompasses a number of different mechanisms that can serve to reduce the exchange of genes between different populations and thus allow them to evolve independently.

The “recognition species concept” is very similar to the biological species concept in that species are defined by interactions among its members (Paterson, 1985). In addition, both concepts try to pinpoint traits that are biologically relevant in species divergence. In the case of the recognition concept, species are defined as groups of organisms that share a common system of fertilization or specific mate recognition system; i.e., the emphasis is placed on what holds species together as a cohesive reproducing group of organisms rather than on what may separate them. The same general concept is embedded in the biological species concept, but the emphasis on mate recognition systems versus isolating barriers does influence how questions about speciation mechanisms are formulated and places more importance on evolutionary processes that positively influence the specific mating interactions between members of a species rather than on the more negative effects associated with preventing mating from occurring between members of different species. In either case, both of these concepts are mechanistically based and represent a prospective view of species distinctions by giving an indication of how isolated groups are now and will continue to be in the future.

Phylogenetic, Evolutionary, and Genealogical Species Concepts

Other more recently derived species concepts rely more heavily on a retrospective view by defining a species in a strictly historical sense as a separate evolutionary lineage that is internally connected through time (i.e., the “phylogenetic species concept” (Cracraft article in Otte and Endler, 1989; Nixon and Wheeler, 1990), the “evolutionary species concept” (Wiley, 1978), and the “genealogical species concept” (Baum and Shaw, 1995); for a good overview, see Harrison article in Howard and Berlocher, 1998; likewise, de Queiroz, 2007). These species concepts are less oriented toward process and identifying specific biological traits that maintain cohesion within species or promote divergence between species and instead are more oriented toward the final evolutionary result – lineage divergence. That is not to say that process cannot be usefully inferred from looking at historical patterns of lineage sorting and splitting (see The Cohesion Species Concept and Incorporation of Genealogical Models), but the emphasis in these particular species concepts is clearly on pattern rather than on trying to incorporate a variety of biological processes into the species definitions themselves.

The Cohesion Species Concept

Perhaps the most inclusive species concept that has been proposed to date is the “cohesion species concept” (see Templeton in Otte and Endler, 1989; see also Templeton in Howard and Berlocher, 1998). This single species concept combines key elements of the biological, recognition, phylogenetic, evolutionary, and genealogical species concepts in order to form a comprehensive framework for defining species

and studying speciation mechanisms. Like the recognition species concept, the emphasis in this case is on defining species based on mechanisms that provide cohesion among members of a population. Unlike the recognition concept, cohesion involves not just shared fertilization systems promoting gene flow (termed “genetic exchangeability” in this model) but also shared historical fates (i.e., belonging to a common evolutionary lineage) as well as shared evolutionary tendencies (i.e., experiencing common selective regimes), both of which will maintain species cohesion (through “demographic exchangeability”) in the absence of gene flow. With this definition, the repertoire of traits important to speciation is broadened beyond traits determined primarily by their effects on reproduction and includes any traits involved in ecological adaptation, regardless of whether or not they directly affect the probability of genetic exchange. Although some would argue this more inclusive, pluralist species concept obfuscates the ability to clearly define species (if anything goes, then what should be the object of study?), in reality, the concept serves as a better starting point for speciation studies precisely because it is not narrowly focused on any one particular speciation mechanism to the exclusion of all others. The practical application of the cohesion species concept has been improved of late by incorporation of historical patterns of genetic variation to use as an explicit framework for both testing hypotheses of species boundaries and investigating speciation processes by modeling how different evolutionary forces pattern this genetic variation under different geographical scenarios (Templeton in Howard and Berlocher, 1998; Templeton, 2007; see also Incorporation of Genealogical Models).

Evolutionary Processes Involved in Speciation

Because genetic change lies at the heart of speciation, the formation of new species involves the action of the same evolutionary processes known to cause genetic changes within populations. The principal evolutionary processes most commonly involved in species divergence are natural selection, genetic drift, sexual selection, and mutation. All of these processes act to change allele frequencies within populations over time and there is no question that they operate during speciation as well. The challenge of speciation studies comes from understanding how these evolutionary processes operate alone and in conjunction with each other within very specific geographical, ecological, behavioral, and genetic contexts. Change any one of these contexts and the same evolutionary process can give rise to very different outcomes and also impact the resulting genetic patterns of speciation.

Natural Selection

Darwin (1872) was the first to popularize the idea that speciation could readily occur through the prolonged action of natural selection, the process by which genetic variants that are better suited to the natural environment increase in frequency while variants that are not well suited decrease. In Darwin’s model of speciation, competition to survive

was thought to be extremely intense. Therefore, the modification of descendants through natural selection served to increase the adaptation of any one population to the environment while also acting to decrease the intense competition between populations by promoting diversification. Over time, speciation would result automatically under these conditions.

Because of the general acceptance of Darwin's idea that natural selection is a potent driving force in species divergence, it is often erroneously considered the only evolutionary force important in species formation. However, natural selection can act to cause change (e.g., through directional or disruptive selection as imagined originally by Darwin) as well as to prevent change (e.g., through balancing selection). Because of the dual nature of selection, speciation studies need to distinguish between those circumstances under which natural selection is promoting speciation versus those where natural selection is a force that actually maintains cohesion and needs to be overcome in order for divergence to occur.

Natural selection's role as a powerful agent for stasis rather than change comes into play in speciation studies in many instances. One particular instance that has been the focus of a prolonged debate in speciation studies surrounds the issue of coadapted gene complexes. Organisms are required not only to adapt to the external environment but also to their own internal genetic environments. Organisms develop and survive as a result of the coordinated control of a complex network of genes selected to function together properly. All possible genetic changes that may help an organism survive in a particular external environment must also function within the constraints posed by this internal genetic environment in order for these changes to be propagated through the population. Genes that have been selected to work particularly well together are called coadapted gene complexes. Once coadapted gene complexes have evolved, it can be very difficult for natural selection to deviate from the established optimum (termed a fitness peak) in order to reach a new optimum that may ultimately be better for the population, but would require the population to experience a temporary loss of fitness (through suboptimal gene interactions) during the transition.

Wright (1932) coined the phrase fitness landscape or adaptive landscape to describe this complicated behavior of fitness as a function of gene interactions. Different genotypic combinations plotted in two dimensions create a complex fitness landscape in the third dimension, much like how a mountainscape appears from an airplane. Mountain peaks correspond to regions of high fitness (for particularly good combinations of genes) separated by valleys of low fitness (for not so good combinations of genes). Natural selection, being somewhat myopic, would work to drive populations up a local peak, but would not be able to take populations across valleys to neighboring peaks of fitness even if those peaks represented greater overall fitness.

Because the true nature of adaptive landscapes is a point of contention for competing models of divergence (see Coyne and Orr, 2004; Gavrillets, 2004), much work in population genetics has been geared toward understanding what the fitness landscape really looks like under a variety of circumstances (for a review, see Wolf *et al.*, 2000). In spite of its

importance, it has been relatively difficult to get a firm handle on the topology of adaptive landscapes partly because at any given moment natural populations tend to occupy a single peak. Advances have been made more recently by studying real and digital microbial populations, which can be followed for tens of hundreds of generations (e.g., see Elena and Lenski, 2003; Clune *et al.*, 2008; Melnyk and Kassen, 2011), and provide more direct information (both actual and theoretical) to help conceptualize the shape of adaptive landscapes and how they influence evolutionary trajectories. Different species themselves represent the successful transition from one optimal state to another that has been frozen in time. Characterizing the genetic transitions that distinguish closely related species gives us clues to the actual shape of the fitness landscape from a complementary perspective (Kao *et al.*, 2010; Wu and Ting, 2004). It also allows us to generate genetic models of speciation that describe how different species are able to make this shift from one fitness peak to another.

Genetic Drift

Given the possible constraints posed by selection acting on coadapted gene complexes, an additional mechanism that would facilitate the movement of a population from one fitness peak to another is often incorporated into models of speciation. Genetic drift is the random change in allele frequencies caused by sampling across generations in a finite population. The actual change in allele frequency caused by genetic drift is random for any given generation; however, the effects of drift will accumulate over time. In the absence of the introduction of new variation through mutation or immigration from another source, genetic drift will serve to decrease the amount of genetic variation present in a population. Because this process is entirely random, how one population responds can differ from how another population responds just by chance, and drift can actually serve to differentiate two populations in the complete absence of natural selection.

In Wright's original model describing adaptive landscapes, genetic drift was one mechanism by which populations could move from one adaptive peak to another. For small population sizes, drift effects can be so strong as to overcome the effects of natural selection. If genetic drift could free the population from the constraints posed by natural selection holding it on one particular fitness peak, then the population could randomly explore the adaptive landscape and possibly fall under the domain of attraction of another fitness peak better than the original one. Individually, genetic drift and natural selection can be very effective for bringing about change. Together they may be even more effective. Although speciation is not specifically addressed in Wright's original model, it does form the theoretical basis for Founder Effect Speciation, which will be discussed in more detail later in this article (see Peripatric or Founder Effect Speciation).

Sexual Selection

Adapting to the natural environment is only one manner in which organisms can increase their ability to leave more

offspring for future generations. Another method is to improve their ability to secure mates through the action of sexual selection. Sexual selection arises from differences in reproductive success caused by competition over mates (Darwin, 1872; Andersson, 1994). Because variance in reproductive success can often be quite high (especially for males), adaptation to the mating environment can sometimes be even more effective at promoting change than adapting to the natural environment and has resulted in the rapid divergence of traits related to reproduction, such as the morphology of male genitalia, sperm composition and abundance, and male secondary sexual characteristics and behavior (Eberhard, 1985; Grant and Grant, 1997; Edwards *et al.*, 2005).

The pressure for sexually reproducing organisms to have compatible reproductive systems ensures that male and female reproductive systems will coevolve. Reproductive systems include behavioral traits related to mate recognition, courtship, and mating as well as physiological traits related to gametogenesis, fertilization, and the production of offspring. Reproductive systems are generally subject to several counteracting evolutionary forces that drive the system in different directions; therefore, mating systems within any particular population tend to reach a stable equilibrium (Lande, 1981; Iwasa and Pomiankowski, 1995). Although the population may be evolving directionally through time, individuals who deviate too much from the norm at any given point along this evolutionary trajectory will generally be disfavored either because of mate discrimination or because of natural selection pressures. Although stabilized with respect to any one population, reproductive systems can be very fluid with respect to the number of stable equilibria that are theoretically possible. Therefore, across several populations, traits related to reproduction are particularly susceptible to changes that can eventually lead to speciation (Lande, 1981; Boake, 2005; Maan and Seehausen, 2011).

The pressure to maintain sexual compatibility (positive male–female coevolution) within sexually reproducing populations is only one important evolutionary consideration for the role of sexual selection in speciation. In addition, there is a second evolutionary process operating that involves antagonistic male–female coevolution which is also very effective at bringing about change, especially in the case of internal fertilization (see Rice in Howard and Berlocher, 1998; Parker and Partridge, 1998). The reproductive interests of males and females are not always identical, especially when there is any deviation from strict monogamy. In these cases, evolutionary conflicts can easily arise. For example, females may mate with multiple males to maximize their own reproductive success, but that creates a battleground for sperm competition among males. To combat the intensified selection for sperm to perform better under these circumstances, the chemical composition of male seminal fluid may evolve to include proteins that act to kill other sperm. These proteins in turn may also have negative pleiotropic effects on the female reproductive system, which is then selected to combat these negative effects. In this scenario, polygamy sets the stage for continual antagonistic selection to occur between male and female reproductive systems. As seen earlier, within any one particular population, antagonistic coevolution will force the male and female reproductive systems to

track each other very closely. However, the effect is very localized and populations that are not in contact with each other have the potential to diverge rapidly with respect to their reproductive physiology (Wu *et al.*, 1996; Rice article in Howard and Berlocher, 1998; Hosken *et al.*, 2009; Prokupek *et al.*, 2010; Lessios 2011).

Mutation

Neither selection nor drift can operate in the absence of genetic variability. Although quite a bit of variability can be generated just through genetic recombination and the random assortment of chromosomes during reproduction, ultimately spontaneous mutation is the primary source of genetic variation. Mutation is considered random with respect to the environmental challenges faced by organisms, although that is not to say it is without bias. Because mutations are important in the context of their effects on the phenotype of organisms, certain phenotypic classes of mutations can be more common than other classes of mutations. In this respect, most spontaneous mutations tend to be deleterious to the fitness of an organism. In addition, mutations are constrained by the chemical nature of DNA or particular properties of the DNA sequence itself, resulting in certain types of changes being more common than others. This can lead to certain classes of base substitutions being more common and to recurring mutation producing the same allele several times independently as is seen for mutations involving slippage during DNA replication of tandemly repeated sequences.

An important consideration for speciation studies is whether new mutations tend to have large or small phenotypic effects (i.e., does divergence occur in leaps and bounds or through the accumulation of numerous small changes?). To model speciation, it is also important to know whether mutations tend to have dominant or recessive effects with respect to fitness – the dynamics of how allele frequencies change over time are dependent on whether or not alleles at low frequencies (as is always the case for new mutations) are readily subject to natural selection or are masked by the effects of other alleles. We also need to know whether new mutations impact more than one phenotypic trait (i.e., have pleiotropic effects) or interact with other loci (i.e., exhibit epistasis) to generate new phenotypes. All of these factors impact the interaction between new mutations and population genetic processes that can influence the change in frequency and ultimate fixation of new mutations in a population.

Common Geographical Modes of Speciation

The crux of speciation studies involves understanding the processes by which a single population splits to form two diverging lineages. Speciation involves the weakening of forces that hold populations together (such as the presence of gene flow, shared mating systems, recurring mutation, and natural selection in common environments) in favor of processes that drive them to diverge (such as the action of genetic drift, mutation, and natural and sexual selection in different

environments in the absence of gene flow). Most modes of speciation incorporate the action of all the evolutionary forces discussed earlier (natural selection, genetic drift, sexual selection, and mutation), but emphasize the operation of certain processes over that of others. Several of these modes of speciation are discussed elsewhere in this volume (see also Coyne and Orr, 2004); therefore the author will focus discussion here on a subset of all possible modes of speciation, concentrating on the specific interaction of different evolutionary forces operating within the context of different geographical and ecological situations, keeping in mind that most speciation events in actuality will be influenced by a combination of modes and evolutionary processes (see Butlin *et al.*, 2008; Fitzpatrick *et al.*, 2008).

Classical Allopatric Speciation

Perhaps the simplest conceptual framework for speciation is the allopatric model. Intuitively, it is easy to recognize that if a physical barrier prevents populations from exchanging genes, they will be free to follow independent evolutionary trajectories. Extensive geographical variation exists (reviewed in Mayr, 1963); therefore, any complete barrier to gene flow most likely means the operation of natural selection will differ to some extent on either side of the barrier. Even in the absence of varying environmental pressures, the continual action of mutation, genetic drift, and sexual selection (see Evolutionary Processes Involved in Speciation) can change the populations relative to each other over time, if they are completely isolated from each other and no longer actively exchanging genes.

Given enough time, speciation will most likely occur under this scenario of no gene flow between isolated populations. Therefore, the interesting issues to explore in allopatric speciation involve examining the relative rates of divergence caused by the action of natural selection, sexual selection, mutation, and drift as well as determining which traits are most easily affected. There are no general rules that can be presented for what happens during allopatric speciation; examples for all possible scenarios (where each of the evolutionary forces has been shown to play a role to a varying degree) can be cited. The specific outcome is very much dependent on the circumstances surrounding the isolation. It has also been readily shown that changes in the reproductive system (both prezygotic behavioral changes in mating propensity and postzygotic physiological changes in the ability to generate offspring) occur rather commonly when populations are separated (reviewed in Coyne and Orr, 2004).

Peripatric or Founder Effect Speciation

Peripatric speciation represents a variation on allopatric speciation. In this case, a small population forms at the periphery of a larger population. This type of geographical isolation can happen anywhere, but is most easy to visualize in the situation of founders colonizing oceanic islands or, more generally, isolated pockets of habitat. Because the founding of peripheral populations can sometimes involve the movement of only a few individuals (or even a single gravid female), this type of

speciation has also become known as founder effect speciation. The emphasis here is on the interaction between genetic drift and natural or sexual selection that occurs during the early stages of speciation.

If a new population is founded by a small number of individuals, just by chance the genetic composition of the founding population may differ significantly from that of the original source population because of genetic drift (see Genetic Drift). The population need not remain small for very long in order for this sampling effect to influence the future evolutionary trajectory of the population. In addition to this immediate genetic change, oftentimes small populations founded in peripheral habitats or on islands also experience changed environments (both the physical environment, including such things as the quality of the habitat, the distribution of resources, or the presence of competitors or predators, as well as the mating environment, represented by a shift in the distribution of available mating types and preferences), creating new selection regimes. Even in the complete absence of new selective environments, the shift in allele frequencies alone can potentially have a profound effect on how the population will respond to selection because of the changed internal genetic environment that results from drift. The combination of shifting gene frequencies by drift and the presence of potentially new selection regimes under this scenario has led some researchers to propose that this type of speciation can occur more rapidly than the more standard form of allopatric speciation which generally involves populations of larger size and less drastic changes in the physical and mating environment on isolation (for reviews, see Hollocher article in Grant, 1998; Templeton, 2008).

The theoretical framework used to justify the conclusion that speciation would be accelerated during founder effect speciation stems directly from Wright's model of an adaptive landscape (see Natural Selection and Genetic Drift). A major underlying genetic assumption that enters into the idea that the random sampling of alleles during the founder event can have a profound effect on the evolutionary trajectory of a population is that epistasis (where interactions between alleles at different loci produce phenotypic effects that are not predicted by the action of the individual allelic effects considered alone) and pleiotropy (where a single locus can directly influence more than one phenotypic trait) are quite common. It is under the assumptions of this type of genetic architecture that fitness peaks of varying heights will exist in the adaptive landscape and where random shifts in allele frequencies can have profound effects (e.g., see Gavrilets and Hastings, 1996; Gavrilets, 2004). If allelic effects governing traits important in speciation are more additive (where interactions between alleles at different loci are minimal), then allele frequency changes will not necessarily impact the trajectory of natural selection greatly.

Much of the debate surrounding the likelihood of founder effects accelerating the process of speciation has focused on the specific influence drift alone would have on the probability of shifting from one fitness peak to another (for a reviews, see the Barton and Hollocher articles in Grant, 1998; Coyne and Orr, 2004; Gavrilets, 2004). What has emerged from these theoretical studies has been the idea that the actual

size of the founding population does not play as crucial a role in determining the probability of shifting from one fitness peak to another as does the underlying genetic architecture of fitness. On the basis of these theoretical results, researchers have begun to shift their focus to evaluating the genetic architecture underlying traits that change during speciation to see how often epistasis is an important component (see Genetic Patterns and Processes of Species Differentiation; see also Phillips, 2008). In addition to the genetic architecture influencing rates of change, the actual nature of the trait itself can affect the type of response that is expected under founder effect speciation. Reproductive isolation (both prezygotic and postzygotic) can be particularly susceptible to rapid change under this scenario because of the tight coevolution of male and female traits that normally occurs via sexual selection (see Sexual Selection). The random sampling of individuals during a founder event can easily move the population away from the stable equilibrium that characterizes the reproductive system in the original population. Reestablishment of a new equilibrium can often involve a radical shift in the mating system of the new population relative to the ancestral one. For sexually selected traits, random genetic drift coupled with sexual selection can act as a particularly powerful mechanism for driving speciation (Lande, 1981; Boake, 2005).

Parapatry and Speciation through Hybridization

Parapatric speciation occurs when new species evolve in contiguous, yet spatially segregated habitats. Unlike allopatric speciation, the populations that are diverging during parapatric speciation maintain a zone of contact and do not cease the exchange of genes completely. In this case, a balance is achieved between continual gene flow and strong natural selection to maintain divergent populations at the two ends of the contiguous habitats. The zone of contact between the two diverging populations, where hybridization between the differently adapted types takes place, is called a hybrid zone (for more general information on hybrid zones, see Harrison, 1993; Hewitt, 2001). There can be a single zone of contact along a linear environmental gradient or several points of contact between habitats that are more patchily distributed. In both cases, the basic dynamics of hybrid zones are similar. In practice, it is generally impossible to distinguish between the situation in which the two populations continually maintained contact during the process of divergence (in which case the hybrid zone would then be considered a primary zone of contact) and the scenario in which the populations were actually allopatric at some point during divergence and then more recently came back into contact (in which case the hybrid zone would be considered a secondary zone of contact).

In either event, hybrid zones are particularly compelling to population geneticists because of the opportunity they present for examining the rate of exchange of genes that may be under different selection pressures in the two habitats. For most stable hybrid zones, the point of contact between the two species represents a semipermeable barrier to gene flow. Examining the distribution of different alleles sampled along a transect through the two habitat types can provide insights into the nature of the selective forces operating during

divergence. The distribution of alleles at loci that have absolutely no effect on fitness will be governed entirely by migration distances and rates of exchange between the two species. Genes that are important for maintaining adaptive differences will show entirely different dynamics relative to these more neutral genes, revealing different patterns depending on the number of genes involved in the adaptations and the strength of selection operating in the two different habitats. Examination of the fates of alleles that shows differential movement across the hybrid zone is also a powerful method for actually mapping the genes responsible for adaptation (see Barton article in Harrison, 1993), which has been expanded to include alleles responsible for early species differentiation even outside the context of hybrid zones (Wu, 2001; Via, 2009).

In addition, hybrid zones represent natural laboratories for determining whether there is speciation by reinforcement. If two species coming into contact exhibit some degree of postzygotic isolation, it is then theoretically possible for selection to act on mating behavior (increasing assortative mating) to eliminate the production of hybrids, thus reinforcing the divergence that has already occurred and completing the speciation process (Dobzhansky, 1940; Servedio and Noor, 2003; Servedio, 2004). Reinforcement is a very appealing concept because it allows postzygotic isolation to play an active role in driving speciation rather than simply being a pleiotropic consequence of divergence. Although evidence of reinforcement occurring in nature has been presented (e.g., Noor, 1995; Nosil *et al.*, 2003), theoretical arguments narrowly limit the range of circumstances under which it is likely to occur and it remains unclear how prevalent the operation of reinforcement may actually be in hybrid zones (reviewed in Coyne and Orr, 2004). The ability of reinforcement to cause complete cessation of gene flow between diverging species is highly dependent on the genetic architecture of mate preference mechanisms, potentially limiting the overall efficacy of reinforcement even further (Bank *et al.*, 2012).

Hybridization is generally perceived as creating zones of tension between the operation of natural selection and gene flow. Speciation is thought to be proceeding through the constant action of natural selection serving to increase adaptation at the two extremes of the zone in the face of a continuous influx of genes that hamper adaptation. Intermediate types that form at the zone of contact are often inferior in fitness and disfavored by natural selection. The actual situation is far more complicated than this simple scenario suggests, even for hybrid zones that generally operate in this fashion (see Harrison, 1993). More importantly, it has become increasingly clear that hybridization does not always play such a negative role in speciation. Instead, it has been shown repeatedly that hybridization can actually provide an important arena for evolutionary innovation (Gross and Rieseberg, 2005; Arnold *et al.*, 2011). In this case, hybridization presents the opportunity for the formation of unique genetic combinations through the mixing of different gene pools. In certain circumstances, these unique gene combinations end up performing better than either parental type in particular habitats and can result in the establishment of novel independent evolutionary lineages and the formation of new species (Donovan *et al.*, 2010).

Sympatric Speciation

Sympatric speciation represents the extreme opposite of allopatric speciation by being wholly independent of geographical context. New species form well within the dispersal range of the ancestral species through divergent natural selection to adapt to alternative habitats. Although ecological adaptation is thought to be the most important process in most cases, sympatric speciation can also occur through the sole operation of sexual selection (Higashi *et al.*, 1999). Because gene flow is known to have a powerful homogenizing effect on populations, it was generally thought that sympatric speciation would be impossible. More recently, modeling and several important case studies have revealed this skepticism to be unwarranted (Berlocher and Feder, 2002; Bolnick and Fitzpatrick, 2007). Most well studied examples of sympatric speciation involve shifts from one host to another that occur in the same geographical region. The genetic adaptations involved in host shifts do not appear to be simple and often involve several different loci that interact to influence a wide variety of traits associated with fitness on a particular host. Often adaptation to one host will preclude the ability to do well on the other, especially if changes in life history are needed in order to track the host species more closely. Host-specific fitness trade-offs will then result, creating the opportunity for divergent selection to cause different host-adapted genotypes to segregate in the population. This type of divergent selection alone will not necessarily result in speciation, but if it is combined with a certain level of host fidelity in which individuals who are reared on a particular host and then return to feed and mate on that same host as adults, then there is a much greater probability that different populations specifically adapted to one host or another will evolve and give rise to new species. Although the focus of sympatric speciation studies typically has been on host shifts, the same principles also apply to adaptation to specific environments and habitat selection more generally (Schluter, 2000).

Genetic Patterns and Processes of Species Differentiation

It is clear from the above discussion that the tempo and mode of speciation not only are affected by geographical and ecological considerations but also can be directly influenced by the nature and genetic architecture of the traits that are diverging. Whether genetic drift can act as a facilitator of speciation during founder effect speciation, or whether specific adaptations generally result in fitness trade-offs that lead to divergence in sympatric speciation, is partially dependent on how commonly epistasis and pleiotropy underlie traits subject to change during speciation. In addition, specific models to explain genetic patterns of postzygotic reproductive isolation (*see* The Genetics of Species Differences) predict very different outcomes depending on whether isolation involves a few or many genes and whether they act recessively or not. To begin sorting through these different possibilities, it is necessary to evaluate the genetic basis of traits that have diverged during speciation to see if any common genetic patterns begin to emerge.

Ultimately, assaying the genetic basis of traits having diverged between species could be helpful in determining whether genetic patterns of change inform us about the evolutionary processes themselves that have played a major role during divergence. If this is true, then genetic patterns of change alone could serve as genetic road maps for navigating the process of speciation. Although we are still in the early stages of research that examines speciation from a strictly genetic point of view, population genetic models investigating what the properties and distribution of these genetic changes would look like under different evolutionary scenarios and across different time scales have begun to be formulated (e.g., *see* Hey, 2006; Mustonen and Lassig, 2009; Wolf *et al.*, 2010).

The Genetics of Species Differences

A remarkable and repeated pattern in speciation is the tendency for interspecific hybrids to be either sterile or inviable (collectively known as postzygotic reproductive isolation). This phenomenon is so striking and common that it forms the central premise of the biological species concept (*see* Most Commonly Used Species Concepts) and has been the focus of intense genetic study over the past several decades. A central organizing principle for the study of the genetics of postzygotic reproductive isolation has been Haldane's rule. Haldane (1922) observed, "When in the F1 offspring of two different animal races one sex is absent, rare or sterile, that sex is the heterogametic sex." As Haldane's rule is obeyed when males are the heterogametic sex as well as when females are the heterogametic sex, the genetic mechanisms that explain Haldane's rule are thought to be fundamental to speciation in all taxa.

Several explanations for Haldane's rule have been posited and an almost equal number have been rejected (reviewed in Hollocher, 1998; Coyne and Orr, 2004). Part of this controversy stems from the difficulties inherent in performing genetic analyses on such traits as hybrid sterility and hybrid inviability. Part also stems from the fact that most researchers naturally sought a single, universally applicable genetic mechanism to account for all cases conforming to Haldane's rule. The general consensus today is that Haldane's rule requires separate explanations depending on whether or not hybrid inviability or hybrid sterility is being considered.

For hybrid inviability, Haldane's rule results because genetic incompatibilities causing inviability that evolve between species tend to act recessively. Given this recessivity, genes causing hybrid inviability will be expressed in the heterogametic sex while remaining masked in the homogametic sex, thus generating Haldane's rule. For hybrid sterility, the explanation is more complicated and involves the joint action of several different processes. As is the case for hybrid inviability, Haldane's rule for hybrid sterility results because genetic incompatibilities causing sterility also tend to act recessively. In addition, however, when males are the heterogametic sex, the evolution of hybrid male sterility is accelerated, most likely due to the additional action of sexual selection driving the rapid divergence of male sexual traits (*see* Sexual Selection; Wu *et al.*, 1996; Rice article in Howard and Berlocher, 1998; Coyne and Orr, 2004). Much detailed work on the

characterization of the genetic basis of postzygotic reproductive isolation (namely male hybrid sterility) has revealed that many genes of small effect are involved and that epistasis is of primary importance for the expression of this trait (reviewed in Wu and Palopoli, 1994; see Wu and Hollocher article in Howard and Berlocher, 1998; Orr, 2001; Coyne and Orr, 2004).

Postzygotic reproductive isolation is only one trait that has generally diverged between species. To formulate a broader picture of the genetic patterns of divergence, it is necessary to compare the genetic architecture of this trait with what is seen for other traits that diverge between species (reviewed in Hollocher, 1998; Orr, 2001). The traits that have been looked at in some genetic detail include interspecific mate discrimination and interspecific differences in secondary sexual characteristics as well as more general morphological traits. Overall, the pattern that emerges is that these traits, too, are governed by many genes of small effect. However, in contrast to what was found for the genetic basis of postzygotic reproductive isolation, epistasis does not play a dominant role in governing the evolution of these species differences. Because both hybrid sterility and hybrid inviability are only manifested when gene interactions are rendered incompatible, the ubiquitous and rapid evolution of these traits reflect the highly integrated nature of gene networks operating in living organisms and the internal selection pressure these networks exert on physiological and developmental systems to constantly adjust to small changes in the genome that accumulate through the normal action of mutation, selection, and drift. Changes in morphological traits, however, are more tightly circumscribed developmentally. Although morphological traits also require integrated gene networks for their proper expression, genetic changes that evolve between species must still be able to operate well within that particular developmental system, whereas hybrid sterility and hybrid inviability signal the breakdown of gene interactions more globally.

Genetic Variation Within Versus Between Species

Comparison of patterns of genetic variation within species versus patterns of genetic variation between species for the same traits can be useful for gaining insights into the evolutionary mechanisms that may have played a role during species divergence (reviewed in Hollocher, 1998; Stern, 2011). If these within-species versus between-species comparisons reveal strong similarities, then generally it can be concluded that speciation proceeded through the same general action of evolutionary processes (in terms of type, direction, and strength) normally operating on these traits within species. In contrast, strikingly different patterns of within-species versus between-species comparisons could reveal the operation of a different set of evolutionary constraints operating during divergence of species than what normally occurs within species.

Interestingly, within- and between-species genetic patterns of sterility and inviability do not show similar patterns at all. Not only is the role of epistasis drastically different between the two comparisons, but also the relative frequency of genes that affect sterility versus inviability is completely reversed depending on whether within- or between-species patterns are

considered. Additionally, within- and between-species patterns of genetic variation for mate discrimination, secondary sexual characteristics, and general morphological traits are very similar with respect to the additivity of genic effects underlying these traits (see Hollocher, 1998; Orr, 2001; Wolf *et al.*, 2010), yet are very different, especially for morphological traits, with respect to whether species differences represent changes in the coding regions of proteins or changes in the upstream regulatory elements governing gene expression, where interspecific differences have been found to be disproportionately tied to changes in gene regulation. This disjunction between the genetic patterns observed within species versus those observed between species suggests that the evolutionary processes that impact standing genetic variation within populations may not be the same that operate over longer periods of time to produce successful species. In other words, time scale does matter and within-species evolutionary dynamics may be very different from the operation of evolutionary processes that ultimately govern the emergence of different species (Stern, 2011).

New Directions for Studying Speciation

Incorporation of Genealogical Models

The classic approach for determining patterns of genetic change between species has been to cross species and analyze the genetic basis of their differences. Most detailed analyses have focused on the genetic bases of postzygotic and prezygotic reproductive isolation. The emphasis of this approach is on understanding how specific biological properties of species change as they diverge from one another. Therefore, the method involves starting with groups of organisms that show interesting differences in evolutionarily important traits and working down to the genetic level to gain insights into speciation mechanisms that may involve these traits specifically.

A very different approach is to use gene genealogies to trace the evolutionary history of genetic variation without regard to the phenotypic effects (in fact, assuming that the genes being investigated are neutral). Population genetic theory involving gene genealogies was originally developed to study the patterns of genetic variation within and among populations of a species to investigate microevolutionary processes such as gene flow, genetic drift, and natural selection. This theory is now being extended from populations up to the species level to investigate how speciation affects patterns of variation within and between species (e.g., Templeton article in Howard and Berlocher, 1998; Hey, 2006; Knowles and Carstens, 2007). This approach examines the genetic structuring of neutral variation within and between species to evaluate the role such things as random genetic drift, continual gene flow, and different geographical patterns play in speciation.

The two approaches described above supply very different information about speciation. Each approach in isolation has contributed substantially to formulating hypotheses about speciation. Using a combined approach could potentially be even more powerful for investigating important issues in speciation. Future studies of speciation would benefit from

continuing to use traditional genetic methods to identify candidate genes for phenotypic traits that may have been critically important in promoting divergence and then analyzing the genealogical structure of these gene regions in the context of the structuring of genes presumed to be neutral to test specific hypotheses about the role the candidate gene regions may have played during speciation. The evolutionary history of genes that contribute directly to phenotypic differences between species is embedded in the evolutionary history of all genes. A combined approach would allow us to tease apart the population dynamics of genes directly involved in speciation from the dynamics of neutral genes. In other words, the genealogical structuring of neutral genes can serve as a baseline measure of population history (supplying information on such things as the geographical patterns of divergence) to compare to the genealogical structuring of genes thought to contribute more directly to the speciation process itself (which would supply information on selective forces important in divergence). In taking this dual approach to understanding the genetics of speciation, we will be able to move one step closer to inferring the evolutionary process of speciation based on the examination of the genetic patterns of divergence.

Incorporation of Developmental Biology

For a complete understanding of the process of speciation, it is not enough simply to understand in broad terms the number of genes involved in species divergence and the general distribution of their effects. As this article has revealed, this approach has been very helpful so far to give us new insights into genetic mechanisms of speciation. However, ultimately it will be necessary to identify the specific products of genes that have changed during speciation to try to understand how the changes in these gene products have specifically led to the changes in the phenotypes that we observe between species. To achieve understanding at all these different levels, it will be necessary to incorporate developmental biology into speciation theories in order to model how specific genetic changes are translated through the developmental program of an organism to give rise to new species. Although the very roots of evolutionary biology are firmly anchored in the field of development, it is only recently that attempts have been made to meld these two disciplines (e.g., see Carroll, 2005; Stern, 2011). The union of these two fields is important not only from a mechanistic point of view for understanding how genes are translated into phenotypes but also for investigating how the structure of developmental systems themselves can serve as direct conduits for the action of natural selection in generating phenotypic diversity.

Conclusions

The study of speciation is a rich and exciting field. Despite being the object of intense study for the past 150 years, speciation studies continue to capture the imagination of evolutionary biologists and offer a wide range of important questions ripe for investigation. The continued vibrancy of the

field comes from its ability to track technological and theoretical advances being made in disciplines such as population genetics and molecular and developmental biology, and to synthesize these distinct approaches to provide fresh perspectives on important ongoing issues in speciation, which due to their innate complexity will never offer simple explanations.

Species Diversity, Overview

A Ross Kiester, Turtle Conservancy, NY, USA

© 2013 Elsevier Inc. All rights reserved.

Glossary

Clique A group of organisms in a food web in which any pair of species in the clique shares at least one prey species. Thus, it is a group of species that have similar diets and are different from other such groups.

Gap analysis A biodiversity policy tool which compares the actual distribution of species and vegetation classes to areas managed for the long-term protection of biodiversity and other classes of land management. Species and classes that are poorly represented in protected areas are gaps in the protection of all biodiversity. Such species and classes are candidates for proactive protection.

Lognormal distribution A statistical distribution which is normal or Gaussian ("bell curve") when the logarithm of the original data is used. Species abundance data from many communities fit this distribution well. The lognormal distribution often occurs as the result of the law of large numbers in which many small factors interact multiplicatively to produce a result such as species diversity.

Simpson diversity index An index of diversity based on species abundance data. If p_i is the frequency of species i in a community of n different species, then

Simpson diversity = $(1 - \sum_{i=1}^n p_i^2)$ and is equal to the probability that two randomly chosen individuals from a

given community are of the same species. This index of diversity is statistically unbiased, making it especially useful in practice.

Species diversity The variability of a group of species classified in some way. For example, individual species can be classified by size and then a species size diversity measure can be developed which expresses the variability with respect to size. The most common classification is by abundance or population numbers. Then species diversity measures the variability of the number of individuals of each species. The Simpson diversity is an example of such an index. Many such indices have been developed for species diversity.

Species richness The number of species occupying a particular area (such as an island) or biological entity (such as a branch of a tree) without regard to any other properties of the species. Species richness may also be expressed as the list of species that generates that number.

Taxonomic rank The level in the Linnaean hierarchy to which a particular taxon or group of species is assigned. For example, mammals are at the level of the class (Mammalia) and hippopotamuses are at the level of family (Hippopotamidae).

Species diversity is one of the most fundamental aspects of biodiversity. However, there are many ways to think about it and ever more ways to measure it. The most basic idea is that of species richness, which is simply a count of the number of species inhabiting a given area or habitat. Species richness may also be thought of as the list of species that were counted. Patterns of species richness in space and time are some of the most foundational data in ecology, biogeography, and paleontology. These patterns both suggest and test theories of species richness dynamics. In addition to species richness, there are many concepts of species diversity. Usually species diversity is formed from species richness by further classifying the species by some attribute, such as abundance, size, or ecological role. When species are classified by abundance or population size, species diversity is the variability in the distribution of individuals into species. This species abundance relation and other measures of species diversity link species richness to many ecological processes such as population dynamics and competition. They also link to evolutionary processes such as adaptive radiation and the evolution of phenotypic plasticity. Species diversity is the building block for the diversity of higher taxa and for the diversity of ecological associations such as communities and biomes. Species diversity is an important policy tool because species diversity is relatively easy to measure and is understandable by many people. Conservation programs and goals are often cast in terms of the number of species that might be protected by a given action.

Introduction

The study of biodiversity often begins with species diversity because it is the most familiar aspect of biodiversity as a whole. Popular interest in biodiversity such as bird watching usually begins with learning to distinguish species, and this leads to a direct appreciation of species diversity. Later, other aspects of biodiversity, such as morphological variants or subspecies, the phylogenetic grouping of species, or the habitats and landscapes associated with particular species, are added to the initial view. Species diversity also lies at the heart of much of evolution and ecology, the sciences most concerned with biodiversity. Each discipline, in its own ways, seeks to explain as much as possible about species diversity and its patterns in time and space. Both sciences use the patterns of species diversity found in nature as tests for ideas about various ecological and evolutionary processes. The relation of species diversity to all other elements of the biodiversity hierarchies of taxa and ecological assemblages (such as communities and ecosystems) is also an important focus of these sciences.

In efforts to conserve the world's biodiversity, species diversity is a key policy concept. It is often the easiest to measure, and it is possible to frame management goals in terms of species diversity. As a practical matter, it is frequently necessary to use species diversity as a surrogate for other levels of biodiversity that may be much more difficult to measure.

Here, we initially focus on species richness (the number of species in a given area) and then discuss other approaches to species diversity. Finally, we discuss the roles of species diversity in biodiversity policy.

Species Richness

The simplest form of species diversity is species richness, which is the number of species which occur in a given area. For example, the species richness of hippopotamuses in Africa is two. However, even within this simple definition there are many important issues. For example, species richness is thought of as a number, but corresponding to each number is also a list of species. The list (*Hippopotamus amphibius*, *Choeropsis liberiensis*) corresponds to the richness number of two for living African hippos.

Computing species richness requires choosing a concept of species and a higher taxon for which a list of species exists. There are many species concepts available, but most are grounded in the theory of evolution and have a theoretical basis. That is, they are entities for which there is a theory that provides methods of determining similarity and difference. The theory is what is used to resolve differences between various workers' classifications. Species are thus in contrast to many other biodiversity entities such as higher taxonomic categories or ecological associations such as communities and ecosystems. These entities are more creations of humanity and their classifications are more artificial. Thus, a vegetation classification is created by ecologists arriving at a consensus for the purpose of accomplishing some work. Since diversity of any entities is a function of the method of classification which creates the units of diversity, theoretical kinds such as species (and genes) offer the possibility of more objective measures of diversity. As a practical matter, calculating species richness depends on the taxonomy available and hence on the taxonomic philosophy of the practitioners for a given taxon. Furthermore, species richness is a function of the rank of the taxon chosen: Species richness will depend on whether one chooses the family Hippopotamidae, the order Artiodactyla, the class Mammalia, and so on.

Species richness is most commonly expressed in terms of area. It may be expressed in terms of a political subdivision of the earth or an ecological subdivision of the earth, or it may be calculated by reference to an equal area grid placed arbitrarily with regard to political boundaries. In all cases, a process of discretization occurs. A species is counted simply as present or absent within a given area. Attributes such as the abundance of the species in the area or the percentage of the area occupied are not taken into account. For equal area grids we obtain an approximation of the underlying continuous variation in the species richness in such a way that we are able to quantify richness. **Figure 1** shows a map of species richness for the reptiles (crocodilians, turtles, lizards, and snakes) of the continental USA. The grid cells are 100 miles on a side or 10,000 square miles in area. **Figure 2** shows hand-drawn isolines of species richness which give a sense of the underlying continuous distribution.

However, species richness may also be expressed in terms of other kinds of aggregates of species. We may determine the

species richness of the parasite load of a single animal or we may determine how many species of epiphytes live on a given tree.

As with any process of discretization, the patterns of species richness revealed are very much a function of the underlying scale of the discretization. **Figures 3** and **4** show species richness of terrestrial vertebrates for the state of Oregon at two scales of discretization. It is clear that the pattern of species richness is scale dependent. Any inferences made from a map of species richness must clearly take the effect of scale into account. It is worth noting that finer resolution maps are not necessarily better for all purposes. There is an uncertainty trade-off between accuracy and comparability in the choice of grid size. A smaller grid size is more accurate, but a larger grid size may produce cells that are more comparable since the effect of data of varying accuracy is smoothed out. For example, a coarser resolution map may provide better insights into large-scale biogeographic patterns because ecological noise may be averaged out. Furthermore, a minimum scale of discretization must be chosen that is appropriate given the accuracy of the individual range maps from which species richness is calculated. The data for **Figure 1** were compiled from the *Peterson Field Guides to Amphibians and Reptiles* (Conant and Stebbins). The range maps in these books show a great deal of cartographic generalization, so a relatively large-scale grid is appropriate. In general, it is a good idea to make the grid cell size several times larger than the spatial scale of the assumed errors in the individual maps.

Most work has been done with species richness as a number because the manipulation and analysis of large lists have only become possible with relatively recent advances in computer science. However, there is clearly more information in the list of species richness than the simple number. Two areas may easily have the same number of species but quite different lists. In general, the further apart two areas are, the fewer species they will have in common. Species richness thus has two components: The absolute number of species in an area and a relative measure of the uniqueness of one area compared to another. This measure is frequently computed by comparing the lists of species from the two areas and noting the number of species that are unique to each area and the number that are common to both areas.

The maps shown in **Figures 1, 3, and 4** are typical of species richness maps derived from the mapped ranges of individual species on which they depend. Calculation of species richness from a set of individual maps assumes that the maps are relatively consistent with regard to accuracy and underlying scale. This in turn requires that the taxonomy of the group under consideration be relatively complete and stable. This requirement is true only for certain taxa and for some parts of the world. In the USA and Europe, vertebrates, butterflies, and trees are generally sufficiently well-known to allow the construction of species richness maps. For the entire planet, only a few groups, such as birds, turtles, and milkweed butterflies, are sufficiently well-known to allow global species richness maps to be constructed. It is difficult or impossible to calculate species richness for poorly known taxa that have many undescribed species or whose taxonomy is controversial. Even for very well-known groups, it is not clear how up-to-date the range maps are since they are often necessarily based on collections made over a long period of time and

almost never on a recent species-wide sampling program. For example, the data used to make the maps of Oregon in [Figures 3 and 4](#) were based on locality records during a 30-year period in order to have relatively complete coverage. Therefore, data for species whose ranges have changed drastically in the past two decades will be out-of-date and consequently the richness maps are in some sense always out-of-date.

There are two ways in which species richness data are accumulated. The first is the slow process of accumulation of the description of new species and the second is a more rapid method in which species richness of a given area is estimated from a statistically designed sampling effort.

As science progresses, our knowledge of species richness increases. This pattern, which is usually an increasing function of time, is called a species accumulation curve. We can think of species as being accumulated on several scales of effort and geography. For example, at the largest scale, that of all scientific efforts taken together for the entire world, we can see a historical accumulation of species. In 1758, Linnaeus recognized 11 species of turtles, in 1889 Boulenger listed 201, in 1992 Iverson listed 257, and in 2010 the Turtle Taxonomy Working Group listed 328 ([Turtle Taxonomy Working Group, 2010](#)). New species of turtles are still being described even though they are among the best known animals. The change from 1992 to 2010 also reflected a general change in the taxonomic philosophy used by turtle systematists. Many taxa that were listed in 1992 as subspecies were elevated to species rank adding species to the total by taxonomic reinterpretation rather than discovery. The number of turtle species has not increased due to any organized or statistically designed effort. The work has simply proceeded as a haphazard attempt at exhaustive enumeration.

In contrast, several attempts have been made to statistically estimate species diversity at a particular location. Usually these efforts determine both the number of species and the number of individuals. In such efforts the number of species caught is a biased estimator since rare species are often necessarily missed. The contrast between haphazard enumeration and statistical estimation is that between more complete knowledge without error estimates and less complete knowledge with error estimates. The best method of synthesizing these two approaches via meta-analysis is an outstanding research problem.

For many taxa and most localities throughout the world, species richness is known only for certain restricted localities such as refuges and research field stations. In some cases, the exact area of knowledge is known, but in others the site may be only generally described. These point locality data are sometimes used to extrapolate species richness over larger areas. This is a new area of research reviewed by [Colwell and Coddington \(1994\)](#), who found many unanswered questions. However, extrapolation may be the best hope of obtaining an estimate of global diversity in the foreseeable future.

Patterns of Species Richness

The most basic pattern of species richness is that between the number of species and the size of the area considered. In general, the larger the area, the more species will be found in it. This species–area relationship frequently takes the form

$S = cA^z$ where S is the number of species, A is the area considered, and c and z are estimated constants. By taking logarithms of both sides of this equation, we find that the logarithm of species richness is a linear increasing function of area. However, many empirical studies have found that the data scatter about a wide band of values of z and that other mathematical forms of the relationship may be equally likely. The analysis of the mechanisms by which area determines species richness is a major line of inquiry for ecologists and biogeographers.

Species richness is very unevenly distributed over the entire Earth. The most important general pattern is that richness increases as one goes from the poles to the equator. [Figure 2](#) shows that this latitudinal gradient in species richness can be quite striking. The average number of species of reptiles increases from 10 at the Canadian border to more than 60 at the Mexican border ([Figure 2](#)). Of course, many taxa are exceptions (penguin species diversity is highest closer to the south pole and there is only one species at the equator), but overall the pattern is strong. Again, studies of the latitudinal gradient in species richness have been a major line of inquiry for ecologists and biogeographers. Another pattern is the peninsula effect whereby species richness decreases toward the end of a peninsula. For example, the number of species of mammals and reptiles decreases in Florida and Baja California as one moves toward the end of these peninsulas. This peninsular pattern can be seen for reptiles on the Florida peninsula in [Figure 2](#).

Species richness varies strikingly in time. The paleontological record provides good evidence that overall species richness increases with time but that there may be massive extinction events that drastically reduce species richness in a relatively short time. At ecological timescales species turnover is common so that the list of species is often changing. The total number of species usually changes less and usually in response to a change in the environment.

Determinants of Species Richness

Over the continuum of scales of time and space, the sciences of ecology, biogeography, and evolution all strive to understand the processes which determine species richness. Indeed, concern for species richness unites these fields (as well as bridging fields such as macroecology and paleoecology). One can easily imagine that they are all part of a single science concerned with species richness. [McKinney and Drake \(1998\)](#) proposed that this field be called the study of biodiversity dynamics and that it should include all kinds of diversity, not just species diversity.

The first question to be addressed is the role of history and the question of equilibrium versus nonequilibrium dynamics. Are the patterns of diversity that we see a result of the vicissitudes of history or of the action of relatively general mechanisms? For example, is the latitudinal gradient in species richness in North America fully recovered from the end of the last ice age. For certain taxa with good dispersal abilities, such as birds or butterflies, it is very likely that they have finished responding to that episode of climate change and are near equilibrium. Other groups, such as salamanders, with very

poor dispersal capabilities may still be in the process of moving into areas opened up at the end of the glaciation and hence their latitudinal gradient may not yet be at equilibrium. Another way of viewing this question is to ask to what extent are there general mechanisms that determine species richness in particular cases and to what extent are there only particular cases. Some ecologists believe that there are only case studies because the details of any particular case overwhelm any instance of a potential general pattern. Others are much more sanguine that general rules and even laws will be able to account for species richness. In any event, for all of the biodiversity sciences the relation between the general and the particular is a difficult problem.

One useful way of dealing with the issue of the general and the particular was developed by Williams (1969), who introduced the distinction between the distant and close views in island biogeography. Island biogeography traditionally has received special attention from students of diversity because the patterns and apparent processes seem to be simpler and easier to understand than those on continents. In Williams' dichotomy the distant view is typified by MacArthur and Wilson's (1963) theory of island biogeography that accounts for the patterns of species richness seen on islands that are of different size and different distances from a source mainland. This model predicts an equilibrium number of species as a function of rates of colonization and extinction. These rates are statistical composites formed from an ensemble of many species and are the mechanisms of the distant view. Here, only the number view of species richness is used. The equilibrium number of species on an island is predicted, but the actual list of species is not. This is not viewed as a problem because the theory predicts that species are constantly turning over and so the list is always changing. The close view is taken by Williams (1969) in his work on the lizards of the genus *Anolis* of the Caribbean or by Lack (1976) in his study of the land birds of Jamaica. In this approach, the focus is on a list of species and the details of the biology of each species examined are considered important. Mechanisms such as colonizing ability, competition, ecological plasticity, and the details of the interactions of species and available habitats are studied on a species by species basis. Adaptive radiation is often considered an important mechanism for generating diversity on a given island. The distant view has the strength of numbers and interprets broad patterns well. It does not account for the actual biology of any particular species. The close view gives detailed accounts of the biology of particular species but generally is not able to predict the number of species. Thus, the distant view focuses on the number version of species richness, whereas the close view is concerned with the actual list of particular species. The close view is not contained within the distant view. Rather it is complementary to it.

A Diversity of Species Diversities

Beyond species richness are an enormous number of species diversities. Generally, these take the form of a species richness of species classified by some property of the species. Species may be classified by abundance (population size), body size, trophic position, taxa, membership in various ecological

assemblages, and in many other ways. As with species richness, the actual number of species in a given class or the list of species in a given class may be analyzed. Because there may be several classes to which individual species are assigned, it is possible to develop an enormous variety of species diversity indices which summarize in various ways the pattern of distribution of species into the classes of a particular classification. The study of these diversity indices, their sampling properties, and the inferences about ecology and evolution that can be drawn from them have been the subject of major scientific activity in the past few decades.

The most common extension of species richness is to the species abundance relation. Here, a set of species is classified by the abundance or population size of each species. Some species are rare and others common; the distribution of all species abundances is called the species abundance curve. Figure 5 shows the species abundance curve for a classic data set of macro-Lepidoptera (mostly large moths) collected by a light trap at Rothamsted in England in 1935. A total of 6814 individuals of 197 species were collected. Thirty-seven species were represented by a single individual, whereas the most common species was represented by 1799 individuals. In this example, the number of classes of the classification is just the number of different integer valued numbers of abundance. All abundances greater than 65 were represented by single individuals. As with many data sets of species abundance, this one fits a lognormal distribution well. The many attempts to

Figure 5 Species abundance curve for macro-Lepidoptera captured by light trap at Rothamsted, England, in 1935. The x's represent the fit of a lognormal distribution. Beyond an abundance of 40 are 26 values ranging from 42 to 1799, each representing 1 or 2 species. Reproduced with permission from Williams CB (1964) *Patterns in the Balance of Nature and Related Problems in Quantitative Ecology*, 324 pp. London and New York: Academic Press.

understand these data both as empirical distributions and as data to test predictions made by theories of community structure have been reviewed by May (1975) and Magurran (1988). Many of the indices fall on a continuum from emphasizing rare species to emphasizing common species. Simple species richness is at one end of this continuum since it weights all species equally. At the other end is the Simpson index, which gives the most weight to the species with the most individuals. Of the many empirical indices of species diversity that combine species abundance data, Lande (1996) found that only the Simpson index is statistically unbiased and leads naturally to measures of similarity between multiple communities. Using both species richness and the Simpson index seems to provide a useful characterization of the species abundance properties of a community.

Living organisms vary enormously in size and it is commonplace that there are fewer large species than small species. Hutchinson and MacArthur (1959) pioneered an ecological approach to understanding the species diversity of body sizes. Figure 6 shows the patterns of species diversity by body size for mammals over three scales in North America. At the scale of the continent, the distribution is unimodal centered on medium and small sizes. At the finest scale (ponderosa pine community of the Oregon Cascade Mountains) the distribution is near flat and shows distinct clumps. This area of research has many competing hypotheses which have been reviewed by Kelt and Brown (1998). Among these hypotheses, a basic idea is that there is more environmental variation at smaller size scales: The world looks more complex to a small beetle than to a larger grazing mammal. This environmental complexity in turn provides a great number of potential niches at smaller scales, allowing coexistence of more species. A provocative analysis by Holling (1993) presented evidence that species sizes of birds and mammals in individual ecological communities are clumped into a small number of discrete, separate size groups. He interpreted this pattern to be the result of a small number of structuring processes ranging from vegetative growth to disturbance dynamics and geomorphological processes which form a discontinuous temporal hierarchy and generate the discontinuous size distributions.

The familiar concept of a food web leads to a classification of species by their position in the web. Here, the basic pattern is that there are fewer species higher in the food web: There are fewer species of top predators than herbivores. Beyond these simple trophic level generalizations, the field is controversial (Yodzis, 1993). One intriguing result concerns the relationship between the species diversity of a web and the number of dominant cliques in the web. A dominant clique of a food web is a group of species in which the predator species share at least one prey species in common and in which the groups are isolated from other such groups and do not share any of their prey species. Figure 7 shows this relatively strong relationship. This pattern may be interpreted to mean that food webs are organized into functional units (groups of interacting predators and prey) and that species diversity increases with the number of such groups.

The species diversity of higher taxa ranging from genera to phyla varies a great deal: The phylum Uniramia, which contains the myriapods and insects, has well over 1 million described species "but many millions more probably await

Figure 6 Species diversity of body size for North America mammals at three scales: (a) continental North America, (b) Sierra Nevada and Cascade ranges, and (c) Oregon Cascades ponderosa pine habitat. Reproduced with permission from Kelt DA and Brown JH (1998) Diversification of body sizes: Patterns and processes in the assembly of terrestrial mammal faunas. In: McKinney ML and Drake JA (eds.) *Biodiversity Dynamics*, pp. 109–131. New York: Columbia University Press.

scientific discovery" (Barnes, 1998, p. 247), whereas the phylum Placozoa apparently has only a single species – *Trichoplax adhaerens* (Barnes, 1998, p. 179). Other ranks in the taxonomic hierarchy vary similarly in their diversity. We are just beginning to understand the patterns of species diversity of higher taxa and clearly this requires a synthesis of evolutionary and ecological theories. Why orchids and beetles are more diverse than many comparable groups is a function of evolutionary plasticity and ecological opportunity. Evolutionary plasticity is a result of both genetic diversity and developmental constraints and opportunities, whereas ecological opportunity is influenced by structural diversity and energy availability. Currently, we lack a detailed understanding of both of these concepts. However, recent paleontological work has demonstrated some interesting patterns of the temporal structure of species diversity of higher taxa. In particular, as origin and extinction probabilities of higher taxa are followed from the Paleozoic to the present there appears to be an accumulation of higher taxa with lower extinction

Figure 7 Species richness versus number of dominant cliques for 40 food webs. Circles represent data from food webs from fluctuating environments, and the solid line is a linear regression for these points. Squares represent data from food webs in constant environments, and the dashed line is a linear regression for these points. Chicago: University of Chicago Press.

probabilities. Certain groups seem to have greater staying power than others and so they are more prevalent today. These patterns offer new possibilities for testing ideas about the evolution of higher taxa species diversity.

At the other end of the taxonomic hierarchy, species may be classified by their internal variability. This variability has something of a hierarchical structure of its own: subspecies, geographic structure, population structure, and genetic structure. Subspecies represent the largest scale of variation within species and are usually thought of as being composed of a major portion of a species range within which several characters are concordant. Geographic variation may also be continuous as with clines or nonconcordant with different characters varying with different geographic patterns. Population structure ranges from continuous to highly fragmented and island-like with many varieties of metapopulation structure in between. Genetic structure follows in part from population structure and provides variability beyond that. The degree of genetic polymorphism shown by local populations provides the most basic variation shown by species. There have been few attempts to quantify species diversity of within-species diversity, although such analyses should lead to further integration of ecological and evolutionary approaches to species diversity.

Summary: Structure of Taxa and Ecological Assemblages

Almost any classification of species results in the fact that species richness of the classes is unequal and often shows

interesting patterns. The description of these patterns and their interpretation in terms of evolutionary and ecological processes is a cornerstone of biodiversity science. Two of the most important kinds of classification are those that classify species by membership in higher taxonomic categories (which, it is hoped, represent phylogenetic groups as well) and into various ecological assemblages such as food webs, communities, landscapes, and biomes. These patterns of species diversity function both to generate and to test hypotheses about the phylogenetic and ecological processes. A great deal of effort has been devoted to analyzing some classifications such as abundance. However, it is clear that attempting to explain the pattern produced by a single classification will inevitably be incomplete. Abundance, body size, and trophic position are strongly related – large top predators are uncommon – and rather than try to explain these characteristics separately, work now focuses on attempting to explain the whole syndrome. The methodology of progressive synthesis outlined by Ford (2000) offers one way to counteract the usual pattern of fragmenting questions. The ultimate challenge to students of biodiversity is to devise better ways of understanding how the phylogenetic and ecological classifications of species diversity interact.

Species Diversity and Biodiversity Policy

Of the many levels of the hierarchy of biological diversity, from genes to the world, species diversity historically has played the dominant role in attempts to maintain and conserve biodiversity. Generally, this has led to a species by species approach such as is exemplified by the Endangered Species Act. This approach has usually been reactive and has been analogized to emergency room medicine. However, recent efforts such as the Gap Analysis Program have focused on sets of species and attempted to lay out proactive approaches. These approaches have in turn been analogized to public health medicine. Generally, it is less expensive to protect a species from extinction while it is relatively common rather than to wait until it is endangered. Both of these approaches use species diversity as a key level of biological diversity (gap analysis also uses vegetation communities as an important level). This focus on species diversity is due to several factors. First, the idea of conserving species is well understood by many people who have a good intuitive understanding of the concept. Second, as mentioned previously, species are scientifically well-defined entities. Finally, species diversity is apparently a good surrogate for many other levels in the hierarchy, such as genes, which are much more difficult to measure in nature. Therefore, it is likely that species diversity will remain a central focus of conservation biology even as other levels of biodiversity become better understood.

Glossary

Cladistic A classification based entirely on monophyletic taxonomic groupings within a phylogeny; taxonomic units that are paraphyletic or polyphyletic are rejected. A cladist is one who practices cladistics, usually in the sense of using parsimony to adjudicate between data from multiple characters in the construction of a cladogram, which is an estimate of the true phylogeny.

Coalescent theory Coalescent theory is a recent development in population genetics, which investigates the merging of gene sequences traced backward in time within gene genealogies.

Cohesion The sum total of forces or systems that hold a species together. The term is used especially in the interbreeding and cohesion species concepts. Cohesion mechanisms include isolating mechanisms in sexual species as well as stabilizing ecological selection, which may cause cohesion even within asexual lineages.

Disruptive selection Selection acting to preserve extreme phenotypes in a population. Speciation usually involves disruptive selection, because intermediates (hybrids between incipient species) are disfavored (*also see* Stabilizing selection).

DNA barcoding A method of delimiting species via clustering of short stretches of DNA sequence data called “barcodes,” usually from mitochondrial DNA.

Gene flow Movement of genes between populations, usually via immigration and mating of whole genotypes, but sometimes single genes may undergo horizontal gene transfer via transfection by microorganisms.

Gene pool The sum total of the genetic variation within a reproductively isolated species population; this term is mostly used by supporters of the interbreeding species concept.

Genomic cluster A synonym for genotypic cluster.

Genotypic cluster In a local area, a single genotypic cluster (or species) is recognized if there is a single group of individuals recognizable on the basis of multiple, unlinked inherited characters or genetic markers. A pair of such genotypic clusters (or species) is recognizable if the frequency distribution of genotypes is bimodal. Within each genotypic cluster in a local region, allele frequencies will conform to Hardy–Weinberg equilibrium, and the different unlinked loci will be in approximate linkage equilibrium. The presence of more than one species or genotypic cluster can then be inferred if the distribution of genotypes is bimodal or multimodal, and strong heterozygote deficits and linkage disequilibria are evident between the clusters.

Isolating mechanisms The sum total of all types of factors that prevent gene flow between species, including premating mechanisms (mate choice), and postmating mechanisms (hybrid sterility and inviability). Modern

authors deny that these mechanisms have necessarily evolved to preserve the species’ integrity as originally assumed, though this may sometimes be the case in reinforcement of premating isolation. Isolating mechanisms are a subset of the factors that cause cohesion of species under the interbreeding and cohesion species concepts.

Monophyletic A grouping that contains all the descendants of a particular node in a phylogeny. Monophyly is the state of such groupings. Compare paraphyletic and polyphyletic. Butterflies (Rhopalocera) and birds (Aves) are the examples of two groups thought to be monophyletic.

Paraphyletic A grouping that contains some, but not all, of the descendants of a particular node in a phylogeny. Paraphyly is the state of such groupings. Compare monophyletic and polyphyletic. Moths (Lepidoptera, excluding butterflies) and reptiles (amniotes, excluding birds and mammals) are examples of two groups thought to be paraphyletic.

Phenetic A classification or grouping based purely on overall similarity. Pheneticists use matrices of overall similarity rather than parsimony to construct a “phenogram” as an estimate of the phylogeny. Examples of phenetic methods of estimation include unweighted pair group analysis (UPGMA) and neighbor joining. Cladists reject phenetic classifications on the grounds that they may result in paraphyletic or polyphyletic groupings.

Phylogenetic Pertaining to the true (i.e., evolutionary) pattern of relationship, usually expressed in the form of a binary branching tree, or phylogeny. If hybridization produces new lineages, as is common in many plants and some animals, the phylogeny is said to be reticulate. Phylogenies may be estimated using phenetics, parsimony (cladistics), or methods based on statistical likelihood.

Polyphyletic Groupings that contain taxa with more than one ancestor. “Polyphyly” is the state of such groupings. Compare paraphyletic and monophyletic. “Winged vertebrates” (including birds and bats) are examples of a polyphyletic group.

Real, reality Two tricky words found frequently in the species concept debate. Reality is typically used to support one’s own species concept, as in: “The conclusions set forth above ... lead to a belief in the reality of species” (Poulton, 1904); similar examples can be found in the writings of Dobzhansky, Mayr, and many phylogenetic systematists. The term reality in this sense is similar to an Aristotelian essence, a hypothetical pure, albeit obscure, truth that underlies the messy actuality; unfortunately, in everyday language real also means actual (curiously, a reality in the first sense may be unreal under the second!). By rejecting the reality of species, one can therefore send very mixed messages: some readers will understand the author to be a

nominalist who merely believes useful terms require no theoretical underpinning; others assume the author is nonsensically using some definition that does not apply to the actual organisms. Here, when the author discusses the reality underlying a species concept, he means it in the first sense, a hypothesis. Many authors of species concepts and some philosophers of science argue that definitions must be underpinned by a theoretical justification or reality. Other philosophers such as Wittgenstein and Popper agree that terms need no such definition to be useful.

Sibling species A pair of closely related, morphologically similar species (usually sister species).

Speciation The evolutionary process of the origin of a new species.

Specific mate recognition systems (SMRSs) Fertilization and mate recognition systems in the recognition concept of species, the factors leading to premating compatibility within a species. Also see cohesion, which is similar to SMRS, but includes postmating compatibility as well.

Stabilizing selection Selection which favors intermediate phenotypes.

Taxonomic inflation The process whereby the numbers of species in the checklist of a group increases due to a change in species concept rather than due to new discoveries of previously unknown taxa.

What are Species Concepts for?

Individual organisms can usually be recognized, but the larger units we use to describe the diversity of life, such as populations, subspecies, species, or genera are not so readily discerned. Taxonomists further group species into genera, families, orders, and kingdoms, whereas ecologists group species into higher structures such as communities and ecosystems. The justification for these group terms is utility, rather than intrinsic naturalness, but as far as possible we attempt to delimit groups of organisms along natural fault lines, so that approximately the same groupings can be recovered by independent observers. However, there will be a virtually infinite number of different, albeit nested, ways of classifying the same organisms, given that life has evolved more or less hierarchically.

Darwin (1859) felt that species were similar in kind to groupings at lower and higher taxonomic levels; in contrast, many recent authors suggest that species are more objectively identifiable, and thus more real than, say, populations or genera. Today, much of ecology, evolution, and biodiversity appear to assume that the species is the fundamental taxon. It has been argued that these fields could be undermined if, say, genera, or subspecies, had the same logical status as species.

Species concepts originate in taxonomy, where the species is "the basic rank of classification" according to the International Commission of Zoological Nomenclature. The main use of species in taxonomy and derivative sciences is to order and retrieve information on individual specimens in collections or data banks. In evolutionary biology, it may also be helpful to delimit a particular kind of divergent evolution, "speciation," which produces a result qualitatively different from within-population evolution, although it may of course involve the same processes. In ecology, the species is a group of individuals within which variation can often be ignored for the purposes of studying local populations or communities, so that species can compete, for example, whereas subspecies or genera are not usually considered in this light. For measuring biodiversity, in conservation studies, and in environmental legislation, species are potentially important units, which we would like to be able to count both regionally and globally.

It would be helpful if a single definition of species could satisfy all these uses, but a generally accepted definition has yet to be found, and indeed is believed by some to be an

impossibility. Yet a unitary definition should be possible if species are more real, objectively definable and fundamental than, say, genera or subspecies. Conversely, even if species have no greater objectivity than other taxa, unitary nominalistic guidelines for delimiting species might be adopted, perhaps after much diplomacy, via international agreement among biologists; after all, if we can adopt meters and kilograms, perhaps we could agree on units of biodiversity in a similar way. In either case, knowledge of the full gamut of today's competing solutions to the species concept problem will probably be necessary for a universal species definition to be found. This article reviews several major proposals currently on the table, and their usefulness in ecology, evolution, and conservation.

Statement of Bias

The author is of Darwin's opinion that the species, like genera and populations, do not have clear boundaries. In evolution and in ecological and biodiversity surveys over large areas, their reality has, in the author's view, been grossly overestimated (Mallet, 2008). In contrast, it is clear to any naturalist that species are usually somewhat objectively definable in local communities. It is the author's belief that confusion over species concepts has been caused by scientists not only attempting to extend this demonstrable local objectivity of the species over space and evolutionary time, but also arguing fruitlessly among themselves about which is the most important apparent reality (or concept) that underlies this spatiotemporal extension of local objectivity. To the author, agreement on a practical, unified species-level taxonomy is possible, but will be forthcoming only if we accept that different species may often lack a unitary biological reality over their geographic ranges and across geological time.

Just as Marxist theory may be wrong, yet remains a convenient approach for studying political history, the author hopes that his own views can provide, even for the skeptic, a useful framework on which the history of proposals for species concepts can be compared. A variety of alternative outlooks can be found by Mayr (1982), Cracraft (1989), Claridge *et al.* (1997), Howard and Berlocher (1998), Hey (2001), and Coyne and Orr (2004).

Darwinian Species Criteria

Darwin's Morphological Species Criterion

Early thinkers assumed that each species had an Aristotelian form or essence, and that variation within a species was due to imperfections in the actualization of this form. Each individual species was defined by its essence, which itself was unvarying and inherently different from all other species essences. Before 1859, it was generally agreed that this essence was descent: all individuals within a species were related by descent, whereas no individuals were descended from individuals in another species. This mode of thought of course precluded transformation of one species into another, and was associated with belief that each form was separately created by God.

Darwin's extensive travels and knowledge of taxonomy led to a realization that the distinction between intraspecific and interspecific variation was false. Individuals could be descended from members of other species: "descent with modification." His abandonment of essentialist philosophy and its species concept went hand in hand with his appreciation that variation itself was among the most important characteristics of living organisms, because it was this variation, which allowed species to evolve. To Darwin, species could be distinguished from divergent varieties if they showed few intermediates: "hereafter we shall be compelled to acknowledge that the only distinction between species and well-marked varieties is, that the latter are known, or believed, to be connected at the present day by intermediate gradations, whereas species were formerly thus connected" (Darwin, 1859, p. 485).

Darwin guessed (correctly) that essentialist species would be hard to give up: "... we shall have to treat species in the same manner as those naturalists treat genera, who admit that genera are merely artificial combinations made for convenience. This may not be a cheering prospect, but we shall at least be freed from the vain search for the undiscovered and undiscoverable essence of the term species" (Darwin, 1859, p. 485). He argued that species were little more than varieties that acquired their claim to a greater reality only when intermediates died out leaving a morphological gap: "... I believe that species come to be tolerably well-defined objects, and do not at any one period present an inextricable chaos of varying and intermediate links" (Darwin, 1859, p. 177). This morphological gap criterion, which seems to have been accepted by many early evolutionists (e.g., Wallace, 1865; Robson, 1928), has been called a "morphological species concept" because Darwin used the gaps in morphology to delimit species; however, it is easy to extend his species criterion to ecology, behavior, or genetics (see Genotypic Cluster Criterion and Assignment Tests).

Polytypic Species

A major revolution in zoological taxonomy occurred around 1900. As the great museum collections became more complete, it became obvious that many apparently distinct species found in different areas intergraded where they overlapped. These replacement species began to be regarded as subspecies within a polytypic species, an idea suggested for geographical varieties by early systematists and Darwinists such as

Wallace (1865). The taxonomic clarification that followed, which allowed identifiable geographic varieties to be named validly below the species level as subspecies, was conceptually more or less complete by the 1920s and 1930s. At the same time, other infraspecific animal taxa such as local varieties or forms were deemed un-nameable in the Linnaean taxonomy. These changes are now incorporated into the International Code of Zoological Nomenclature. Similar ideas were promoted in botany by G.L. Stebbins (see Mayr, 1982), although in the International Botanical Code local varieties and polymorphic forms remain valid and nameable taxa.

The Rephilosophization of Species, the "Interbreeding" Concept

In January 1904, Poulton read his famous presidential address – "What is a species?" – to the Entomological Society in London (see historical analysis by Mallet, 2004). Following up on ideas raised (but immediately dismissed) by Wallace (1865), Poulton proposed "syngamy" (i.e., interbreeding) as the true meaning of species. Poulton and Wallace were both particularly knowledgeable about swallowtail butterflies (Papilionidae). In swallowtails, there exist strong sexual dimorphisms: the female color pattern often mimics unrelated unpalatable butterflies whereas the male is nonmimetic. The females themselves are sometimes polymorphic (e.g., in *Papilio memnon* and *Papilio dardanus*), each female form mimicking a different distasteful model. Under a crude morphological criterion, each divergent form could be designated as a different species, whereas mating observations in the wild showed that the forms were part of the same interbreeding group. A related idea was promoted by the botanist Lotsy, who termed the interbreeding species a "syngameon" (Lotsy, 1917). In the 1930s, Dobzhansky studied morphologically indistinguishable sibling species of *Drosophila* fruit flies and concluded that Lotsy's approach had some value (Dobzhansky, 1937). A member of a species will rarely, if ever, interbreed with a member of a sibling species; each chooses mates within its own species. Dobzhansky proposed his own interbreeding species concept, later popularized by Mayr as the "biological species concept," so named because interbreeding within species, coupled with reproductive isolation between species, was considered the single true biological meaning or reality of the term species (reviewed by Mayr, 1970, 1982).

A short definition of the biological species concept is as follows: "species are groups of interbreeding natural populations that are reproductively isolated from other such groups" (Mayr, 1970). The biological concept of species was not so much new as a clarification of two distinct threads: (1) a local component, the Poulton/Dobzhansky interbreeding concept, and (2) a global component, which extended the interbreeding concept to cover geographically separated populations of actually or potentially interbreeding subspecies, as in the preexisting idea of polytypic species.

This extended interbreeding concept was, until about 30 years ago, almost universally adopted by evolutionists. The species concept problem appeared to have been solved; species were interbreeding communities, each of which formed a "gene pool" reproductively incompatible with other such

communities. The new concept answered both perceived problems of Darwin's morphological approach: (1) That mutants and polymorphic variants within populations might be considered as separate species. (2) That sibling species might be misclassified as members of the same species. The new approach was promoted in a long series of books and articles by Dobzhansky, Mayr, and their followers. Mayr, in particular, was highly influential by justifying the taxonomic application of the polytypic species criteria in terms of the new concept of "gene flow." The new species concept was considered necessary for understanding speciation in relation to the population genetics. Darwin was hereafter deemed to have failed to solve, or even address the origin of species in his 1859 book, because he supposedly had not appreciated the fundamental importance of interbreeding (Mallet, 2010a).

To take this view, it was necessary to see species in a new post-Darwinian light. Instead of species being defined simply, using man-made criteria based on demonstrable characters such as gaps in morphology, species became defined by processes important in their own maintenance, that is by means of their biological function (Mayr, 1982). Significantly, the philosophical term "concept" came into vogue along with these new ideas about species, and the term "species problem," which hitherto had referred to the problem of how species arose (Robson, 1928), became instead the problem of defining what species were. The important features of species defined by the "biological species concept" were that they were protected from gene flow by physiological isolating mechanisms (Dobzhansky, 1937) or "reproductive isolating mechanisms," including prezygotic mechanisms (ecological, mate choice, and fertilization incompatibilities) and post-zygotic mechanisms (hybrid inviability and sterility caused by genomic incompatibilities). Curiously, by going beyond simple, Darwinian character-based identification of species, the "biological concept of species" became less universally applicable in biology; for example, Dobzhansky (1937) simply concluded that asexuals (between which no interbreeding is possible) could not have species.

Poulton, Mayr, and Dobzhansky emphasized that their new concept was based on the reality that underlay species, rather than being merely a criterion useful in taxonomy. In this new philosophical approach, taxonomic criteria became separated from conceptual issues, and practical delimitation took on a secondary role. The same division between concept and criteria is still evident in most discussions of species concepts today, for example in the "general lineage concept" (de Queiroz, 1998; see Evolutionary and Lineage Concepts). The concept was seen to be true from first principles, and became untestable: violations of the criterion of reproductive isolation, such as hybridization, intermediates, and inapplicability to many plants and asexuals caused problems in classification, but did not disprove or even challenge the underlying truth of the concept itself. These imperfect actualizations of species' true reality were expected in nature. Mayr claimed that the biological concept would do away with "typology" (his term for species definitions based on a fixed, unvarying type or Aristotelian essence), but in many ways it can be seen that the biological concept reverts to a new kind of essentialism, where evolutionary maintenance via interbreeding is the underlying reality, or essence of species.

Alternative Species Concepts

It is interesting that exactly this kind of search for the essence of species had already been criticized by Darwin (1859), as we have seen (see What are Species Concepts for?). In his chapter "Hybridism," Darwin specifically argued against using post-zygotic isolation (hybrid sterility and zygote inviability) as cut-and-dried characteristics of species. In this discussion, he made no mention of prezygotic isolation, another component of the reproductive isolation that characterizes species under the biological concept. However, we can infer that Darwin, the discoverer of sexual as well as of natural selection, would almost certainly have argued that mate choice, along with hybrid sterility and inviability, are all found within as well as between species, although to a lesser extent. Oddly, Mayr (1982, p. 269) claimed that Darwin treated species "purely typologically (i.e., as an essentialist) as characterized by the degree of difference," and also that Darwin "had strong, even though perhaps unconscious, motivation ... to demonstrate that species lack the constancy and distinctiveness claimed for them by the creationists." Whether or not it is reasonable to criticize Darwin in such a contradictory way can be debated, but it is clear that Mayr's proposition that interbreeding was the true essence or reality of species immediately laid itself open to debate. Although the interbreeding concept had a long run (and still does), proposals for different kinds of biological reality of species were eventually forthcoming. By proposing a single reality for species, Poulton, Dobzhansky, and Mayr reopened Pandora's box of alternative essences deemed more important by other biologists.

Ecological Species Concept

Asexual organisms such as the bdelloid rotifers can clearly be clustered into groups recognizable as taxonomic species, very likely because competition has led to the extinction of intermediates (Hutchinson, 1968; Fontaneto *et al.*, 2007). However, distinct sexual forms such as oaks (*Quercus*), between which there are high rates of hybridization, can remain recognizably distinct even where they cooccur. This suggested to van Valen (1976) that the true meaning of species was occupancy of an ecological niche or adaptive zone rather than interbreeding, yielding an ecological species concept. It became clear to Mayr by 1970 also (see Mayr, 1982) that gene flow could not unite every population in a polytypic, biological species' range, and that stabilization of phenotype might be effected by ecologically mediated stabilizing selection (see Recognition Concept of Species and Cohesion Concept of Species) rather than purely because of gene flow.

Recognition Concept of Species

An important attack on the biological species concept came from Hugh Paterson in the early 1980s. His claims were twofold: First, that the Dobzhansky/Mayr term "isolating mechanisms" implied that reproductive isolation was adaptive, which Paterson felt was unlikely. Second, that the true reality underlying species was prezygotic compatibility, consisting of mating signals and fertilization signals. According to

Paterson (1985), this compatibility is strongly conserved by stabilizing selection, whereas isolating mechanisms such as hybrid sterility or inviability are nonadaptive and can be argued to be a result rather than a cause of species separateness. To Paterson, the true reality of species must be adaptive, and the idea that species are held together by beneficial isolating mechanisms was a fallacious argument that relied on adaptation at the whole species level (Mallet, 2010a, b). Paterson termed his idea of species the “recognition concept” versus Mayr’s “isolation concept,” and its important characteristics specific mate recognition systems (SMRSs) instead of isolating mechanisms. Species were defined as “that most inclusive population of individual biparental organisms, which share a common fertilization system” (Paterson, 1985).

The idea is generally recognized as a useful critique and has gained strong currency in some circles. However, it appears also that SMRSs are more or less the inverse of prezygotic isolating mechanisms, and that the recognition concept therefore differs practically from the biological species concept mainly by focusing on the subset of traits acting before fertilization. In addition, the interbreeding concept had always stressed a common gene pool and compatibility within a species, as well as isolation between species.

Species Concepts Based on History

Monophyly

The rise of cladistic methods revolutionized systematics by proposing that all classification should be based on the idea of “monophyly.” This new system formalized the principle that paraphyletic and polyphyletic taxa were unnatural groupings, which should not be used in taxonomy. It was natural to attempt to apply this idea throughout systematics, all the way down to the species level, leading to a monophyly criterion of species (Hennig, 1966), a type of phylogenetic species concept (see Diagnostic Species Concept). Species were seen as forming when a single interbreeding population split into two branches or lineages that did not exchange genetic material. In a somewhat different formulation, the cladistic species concept, species are branch segments in the phylogeny, with every branching event leading to a new pair of species (Ridley, 1989). Otherwise, if only one of the two branches were recognized as new, the other branch would become paraphyletic.

Perhaps the main criticism of this idea is that it could, if applied in taxonomy, cause great nomenclatural instability. Monophyly exhibits fractal self-similarity and can exist at very high or very low levels of the phylogeny, so the precise level at which species taxa exist becomes unclear. Suppose that a new monophyletic form is discovered overlapping with, but remaining distinct from, a closely related local form in the terminal branches of an existing species. Recognition of this taxon as a species would leave the remaining branches within the original species paraphyletic. Many other branch segments would then need to be recognized at the species level, even if they interbreed and have reticulate, intermingling relationships. Many phylogenetic systematists therefore adopt a different phylogenetic concept, the diagnostic concept (below), which can allow paraphyly at the species level.

Diagnostic Species Concept

The motivation for the diagnostic concept, usually called the “phylogenetic species concept” by its adherents, was again to incorporate phylogenetic thinking (Hennig, 1966) into species-level taxonomy. There are many cases of hybridization between taxa on very different branches of species-level phylogenies, which suggests that interbreeding and phylogenetic realities conflict. Cracraft (1989) also noted that many bird taxa, normally thought of as subspecies, were far more recognizable and stable nomenclaturally than the polytypic species to which they supposedly belonged (see Genotypic Cluster Criterion and Assignment Tests). Cracraft therefore argued that the polytypic/interbreeding species concept should be rejected, and, in its place, we should use a diagnostic criterion in the form of fixed differences at one or more inherited characters. A phylogenetic species is an irreducible (basal) cluster of organisms, diagnosably distinct from other such clusters, and within which there is a parental pattern of ancestry and descent (Cracraft, 1989). According to Cracraft, species defined in this way are the proper basal, real taxa suitable for phylogenetic analysis and evolutionary studies.

Of course, if diagnostic criteria are applied strictly, rather small groups of individuals, or even single mutant specimens, might be defined as separate species, leading to potentially unbridled taxonomic inflation. Cracraft recognized this and argued that such trivial diagnosable groups would have no parental pattern of ancestry and descent, that is, they are not proper populations. However, this qualification appears similar to an interbreeding criterion of species, whereas the whole approach of using diagnostic characters was an attempt to get away from interbreeding.

Most evolutionary biologists balk at the idea of speciation being merely the acquisition of a new geographically diagnostic character, a DNA base pair or color pattern change perhaps (Harrison, 1998). Speciation is only a different, or special, kind of evolution if the new species is a distinct population, which can coexist locally with its sibling or parent population without losing its integrity.

Characters used to diagnose phylogenetic species may not be shared derived characters; they may be primitive (plesiomorphic) characters, or they may have evolved several times. Therefore, phylogenetic species need not be monophyletic, and could presumably be paraphyletic and perhaps polyphyletic. Cracraft appears confused on this matter: on one hand, he claims that phylogenetic species “will never be nonmonophyletic, except through error” (Cracraft, 1989, p. 35), but on the other hand he recognizes that “their historical status may (sometimes) be unresolved because relative to their sister species they are primitive in all respects. Whether they ... (are) truly paraphyletic ... is probably unresolvable” (Cracraft, 1989, p. 35). It seems odd to allow a phylogenetic species even to be paraphyletic (let alone polyphyletic), because paraphyly and polyphyly contravene the basic tenets of phylogenetic systematics, and because one of the main justifications for a phylogenetic species concept is that species defined via other concepts might sometimes be paraphyletic: “the biological species concept cannot be applied to the *Thomomys umbrinus* complex unless one is willing to accept paraphyletic species,

and to do so would be a de facto admission that biological species are not units of evolution" (Cracraft, 1989, p. 46; also see Davis, 1997, p. 374). The phylogeneticists' resolution of that problem, using diagnostic characters, leads to the same difficulty all over again! This rather glaring logical inconsistency considerably undercuts the argument for a diagnostic species concept.

In spite of these logical problems, Cracraft highlighted genuine and important practical problems with the polytypic application of the interbreeding concept, and as a result this phylogenetic species concept has been very influential. Recently, many molecular systematists, including botanists (Davis, 1997), have taken up Cracraft's suggestion and used diagnostic differences between geographic populations, in some cases at single DNA base pairs, as evidence that two forms are separate species even if they intergrade freely at the boundaries of their distribution. Ornithologists and primatologists in particular have used diagnostic characters to reassign many taxa long thought of as subspecies to the level of full species, resulting in rather severe taxonomic inflation (Isaac *et al.*, 2004).

Genealogy

Other phylogenetic systematists continued to be interested in monophyly-based species concepts. A problem with a monophyly concept is that a single, true phylogeny of taxa may, in a sense, rarely exist: a phylogeny of species can be seen as an abstraction of the actual genetic history, consisting of multiple organismal genealogies (Hennig, 1966), or multiple gene genealogies (Avice and Ball, 1990; Maddison, 1997), some of which may undergo genetic exchange with other taxa. There is now good evidence that occasional horizontal gene transfer and hybridization may selectively cause genetic material to flow between unrelated forms (Mallet, 2008). Furthermore, there are multiple gene lineages within any population, so that, if such a population were to become geographically or genetically split into two distinct forms, it would take some time before each population became fixed for different, reciprocally monophyletic gene lineages at any single gene. The idea of monophyly for whole genomes then becomes hard to define, especially near the species boundary. However annoying, phylogenetic methods and evolutionary theory must face up to these facts (Avice and Ball, 1990; Maddison, 1997). Instead it was suggested that monophyletic species could be defined if they formed exclusive sets, where each member was related more closely to members of its own species than to any members of another species. Species were argued to be formed at the fuzzy boundary between reticulate (within species) and divergent (between species) organismal genealogies; it was suggested that such species could be delimited when a consensus of multiple gene genealogies indicated reciprocal organismal monophyly. This was called the "genealogical species concept" (Baum and Shaw, 1995).

Critics argue that this idea has many problems in common with other monophyly concepts of species (Davis, 1997; Hudson and Coyne, 2002). Geographic forms that have become isolated in small populations or on islands, say, could rapidly become fixed for gene lineages, and become

viewed as separate species without any biologically important evolution taking place. Conversely, clearly distinct sister taxa such as humans and chimpanzees still share gene genealogy polymorphisms at some genes such as the human leukocyte antigen (HLA) complex involved in immunological defense, and might therefore be classified as the same species under genealogical considerations.

Bayesian Species Delimitation

A new approach employs a Bayesian analysis to compare competing species models using multilocus sequence data (Yang and Rannala, 2010). For example, the one-species model assumes that the gene trees for different loci fluctuate according to the standard neutral (coalescent) theory within a single population, whereas the two-species model assumes two species that diverged some time ago, so that there will be more concordance among the gene trees across loci. The two-species model assumes a "biological species concept," i.e., that gene flow ceased at some time in the past. The competing species models are compared using their posterior probabilities, allowing one to assess if sequence data are compatible with the one-species model, or whether the two-species model has to be invoked. It should also be emphasized that more than two species can be readily accommodated in this hypothesis testing framework.

Concordance of gene trees across multiple loci is used as evidence to infer species-level monophyly (as in the reciprocal monophyly concept of the section Monophyly), but the method does not rely on reciprocal monophyly of each gene tree. It accounts for random fluctuations in the coalescent process in both the extant and extinct species and thus takes into account genealogical concerns of the section Genealogy. Its statistical approach, however, accommodates uncertainties in the gene trees, unlike the genealogical species concept, the suggested implementation of which ignored phylogenetic errors in the gene trees when constructing the consensus. Simulations suggest that small amounts of gene flow ($Nm < 0.1$ migrants per generation, say) has little impact on the behavior of the method. The method thus should recognize distinct species despite occasional hybridization (Zhang *et al.*, 2011).

This method represents a considerable advance in sophistication of analysis of genomic data to delimit species. In that it employs Bayesian posterior probability to infer the number of species taxa from a set of data, it is similar to "assignment tests" to detect multilocus genotypic structure (see Alternative Species Concepts) but instead it uses neutral coalescent modelling rather than a simpler model of free recombination and assortment within species. The method currently requires adoption of a guide tree of taxa: populations that are potential species and their relationships must be defined before statistical decisions to award species status can be made. It is arguable that Bayesian delimitation may view spatially separate populations as species simply because they happen to have separated some time ago, and not because they have speciated in the sense of their ability to overlap without fusion. It may thus exhibit the same problems (if they are viewed as problems) as the monophyly concept of species (see Monophyly).

Combined Species Concepts

Evolutionary and Lineage Concepts

Faced with the problem of studying the evolution of species through time, the paleontologist [Simpson \(1951\)](#) proposed his evolutionary species concept, in which a species is “a lineage (an ancestral–descendant sequence of populations) evolving separately from others and with its own unitary evolutionary role and tendencies.” In other words, Simpson combined the idea that species were historical lineages with the concept of their evolutionary and ecological role. The key essence here appears to be “evolutionary independence.” This concept appeals to phylogenetic systematists and paleontologists alike, because of its historical dimension, and to neontologists because of its acknowledgment that biological mechanisms are what make the species real. [De Queiroz \(1998\)](#) is one of the more recent reviewers to propose that a single concept, which he calls “the general lineage concept,” under which species are segments of population-level lineages, underlies all other species concepts. According to de Queiroz, the other apparently competing species concepts merely emphasize different characters or criteria for species delimitation, but all acknowledge implicitly or explicitly that evolutionary separateness of lineage is the primary concept. This is a nice ideal, but vague terms like “evolutionary independence” have little logical force in their application to actual forms that hybridize or undergo genetic exchange. Furthermore, by failing to delimit where species are along the continuum of diverging lineages, de Queiroz side-steps the whole issue of species definition rather than solving it. The main content of [de Queiroz's \(1998\)](#) idea seems to be that species emerge gradually. However, this particular finding had been clarified 140 years earlier.

Cohesion Concept of Species

In similar vein, [Templeton's \(1998\)](#) “cohesion concept” combined a number of competing ideas of species. He accepted criticisms of the interbreeding species concept, and attempted to correct it by infusing ideas from the evolutionary, ecological, recognition, and genealogical concepts. Templeton argued that a combination of ecological and reproductive cohesion is important for maintaining a species' evolutionary unity and integrity. As well as applying to asexual taxa (too little sex), Templeton also applied his idea to species like oaks that undergo frequent hybridization and gene flow (too much sex for the interbreeding concepts). He further argued that separateness of genealogy is another important characteristic of species.

We are perhaps nearing the apogee of the species debate with these combined concepts. By incorporating evolutionary, phylogenetic, and genealogical origins together with every possible biological means by which the distinctness of species is currently maintained, these combined concepts cover all the bases. One can acknowledge that species evolve and are maintained as cohesive wholes by all of these multifarious processes; yet at the same time species can, and perhaps should be seen as separate from their histories of origin and from current reasons for their integrity. If groups with very different and conflicting biological and evolutionary characteristics are all considered species, there should exist a simpler

criterion that unites them. It can also be argued that to conflate the origin and evolutionary role of a taxon with the definition of that taxon itself may lead to circularity, particularly in conservation or ecological studies, or when investigating speciation.

Dissent: Maybe Species Are Not Real

Throughout the history of the species debate, starting with Darwin, there have been some who argue that species are not individual real objects, but should instead be considered as man-made constructs, merely useful in understanding biodiversity and its evolution. These people are not necessarily nihilists, who deny that species exist: they simply argue that morphological and genetic gaps between actual populations would be more useful for delimiting species than inferred processes underlying evolution or maintenance of these gaps. By their refusal to unite these ideas under a single named concept, this silent majority has rarely found a common voice.

Taxonomic Practice

Taxonomists are on the front line of the species battle, because it is they who ultimately decide whether to lump or split taxa, and at what level to name them as species. If the objectivity and individuality of species as the primary taxon exists, taxonomists' activities do not seem to have been made any easier. Many taxonomists have simply ignored or denied belief in the evolutionary reality of species. In any group, it is probably true to say that at least 10% of taxonomic species are subject to revision because of the practical difficulties in delimitation.

For this reason, since the rise of the polytypic/interbreeding species concept, there has been little impact of the postwar species concepts on practicing taxonomists, even while the debate raged around them, at least up until the 1980s. Procedure, at least in zoology, was more or less as follows: geographic variants, which blended (or were thought to be able to blend) together at their boundaries were united within a single, polytypic species, unless morphological or genetic differences were so great that it seemed necessary to recognize two species. However, whenever two divergent forms differing at several unrelated traits overlapped spatially, they were recognized as separate species even if a few intermediates suggested some hybridization or gene flow. Some taxonomists regarded subspecies as artificial taxa to be avoided, and may either have ignored geographic variation, or elevated subspecies of formerly polytypic species to the rank of full species. But good taxonomic practice on species remained broadly similar across most branches of systematics, and involved careful analysis of multiple, chiefly morphological character sets tested in large samples of specimens collected from as many geographic regions as possible.

This view on species and subspecies had led to a steady reduction in the numbers of recognized species in zoology, as more and more dubiously separated taxa, previously ranked as species, became inserted as subspecies or local populations into larger and larger polytypic species. Recently, however, the diagnostic version of the phylogenetic species concept (*see* Diagnostic Species Concept) has been making strong inroads into

zoological nomenclature, with the result that counts of species on continents are again climbing as former subspecies are re-elevated to the species level, in spite of intergradation at their boundaries (Isaac *et al.*, 2004). However, the situation could get much worse; many *Heliconius* butterflies, for example, have over 30 geographic subspecies per species, all of which can be diagnosed easily. The numbers of bird and butterfly species could easily increase 2–10 times in some groups if the diagnostic criteria were generally adopted, and indeed in some well-known groups, for example primates, a doubling of species numbers has already been observed. Most of these increases have come from reclassification of known subspecies or populations, rather than from discovery of new populations (Isaac *et al.*, 2004). The one reality that is clear in species-level taxonomy is that the species is not real enough to remain at the same taxonomic rank while fashions in species concept change. This provides evidence that actual species taxa have been and still are man-made groupings that do not employ objective biological or evolutionary essences, even if such essences exist.

Populations Are Evolutionary Units, Not Species

Botanists deal with geographically variable organisms with low powers of dispersal, and have tended not to be as happy with the polytypic/interbreeding concept applied with such apparent success in zoology. Meanwhile, the strong surge in experimental population genetics and evolutionary studies that followed the books by Dobzhansky, Mayr, and Stebbins has led to a greatly improved understanding of gene flow in natural populations. Gene flow, even in quite mobile animals such as birds or butterflies, may not unite distant populations into a common gene pool. If such populations only rarely exchange genes, then gene flow across the range of a continental species is clearly insufficient to explain species integrity, because it would be outweighed easily by weak local patterns of adaptation or genetic drift (Endler, 1977).

This increasing input of population biology into systematics and evolution led to the proposal by Ehrlich and Raven (1969), Levin (1979), and others that species are not real biological units at all; instead, local populations are the only real groupings united by gene flow within a common gene pool, and which adapt to local conditions, compete, and so on. Any homogeneity of ecological niche or genetics over the range of a species might be owing either to recent spread and simple evolutionary inertia or to similar stabilizing selection everywhere. To these authors, species exist and are real in local communities, but it is fallacious to treat distant populations in the same way (*see* Genotypic Cluster or Genomic Cluster Criterion).

This viewpoint is generally understood and respected by population biologists, but curiously has not been incorporated explicitly into current thinking on species in systematics and evolution. Perhaps there is a sneaking suspicion that even very weak levels of gene flow may explain species integrity over wide areas.

Phenetic Species Concept

In the 1960s and 1970s, a major systematics movement proposed numerical methods in taxonomy now usually referred

to as “phenetics.” Pheneticists, as they were called, argued that taxonomy and systematics should be based on multivariate statistical analysis of characters rather than on underlying evolutionary or biological process information. If taxa were defined by nonevolutionary criteria, studies of evolution would be freed from the tautology of testing hypotheses about processes, when those same processes are used as assumptions in the definitions of the taxa under study. Species, like other taxa, would be defined in numerical taxonomy on the basis of multivariate statistics, as clusters in phenotypic space (Sokal and Crovello, 1970).

Phenetics was reviled by those who believed that classifications should be phylogenetic. However, for species the approach is closely similar to the intuitive methods adopted by the most actual taxonomists, who use multiple morphological or genetic characteristics to sort individual specimens into discrete groups between which there are few intermediates (*see* Ecological Species Concept). Some large areas of practical taxonomy are based purely on this phenetic approach. Bacterial systematists, for instance, use multiple biochemical tests to assign microbes to species taxa (Claridge *et al.*, 1997). The usefulness of this taxonomic method is attested by its success in hospitals for predicting pathogeneticity and antibiotic sensitivity.

Phenetic classifications based on morphology introduce the danger that, if convergent characters are used as data, one may group unrelated forms into polyphyletic taxa. In addition, single gene polymorphisms and sexual dimorphism can affect multiple morphological characters. This could lead to a recognition of multiple species within polymorphic populations. Sibling species, however, could be lumped into the same species using a phenetic approach, unless a set of highly diagnostic characters could be found. Nonetheless, these problems are mainly due to the lack of characters found in morphological datasets. Phenetic methods have proved much more successful in distinguishing unrelated, although cryptic, taxa from polymorphic forms when coupled with molecular genetics techniques developed since the 1960s, including allozymes and DNA-based methods (Avice, 1994).

Genotypic Cluster Criterion and Assignment Tests

For morphological or genetic gaps to exist between species, gene flow (if any) between species must be balanced by an opposing force of disruptive selection. In his own work, the author had studied hybrid zones between geographic forms of butterflies, and the author attempted to show that a practical statistical definition of species versus geographic races could be constructed using morphological and genetic gaps alone, rather than employing the phylogenetic or evolutionary processes that caused the gaps to exist.

However, to define species by means of the gaps between them requires consideration of the nature of the gaps to avoid falling into the trap of defining polymorphic forms as separate species, or of lumping sibling species. Rather than merely using external morphology, in difficult cases the author proposed that we could consider genetics as well. DNA has a digital, rather than analog code, so there are genetic gaps between virtually any pair of individuals. Clearly, then, we

cannot use just any discreteness at the genetic level to define species. Separate sexes and polymorphic female forms of mimetic *Papilio* butterflies also have gaps between them in exactly this way. A genetic element, which may be a single base pair, an allele at a gene, the entire mitochondrial genome, a chromosomal rearrangement, or perhaps a sex chromosome, may determine the genetic or morphological differences between such polymorphic forms.

To be considered part of a single local population, and therefore part of the same local species, we expect that polymorphic genetic elements like mimicry genes and sex chromosomes will be approximately randomly combined with polymorphisms at genetic elements found on other chromosomes or extrachromosomal DNA. Each individual may be a distinct multilocus genotype, but we recognize a single grouping of genotypes because polymorphisms at one genetic element are independent of polymorphisms at others. Conversely, if alleles at one locus are strongly associated with alleles at other, unlinked elements (i.e., linkage disequilibrium or gametic disequilibrium), we have evidence for more than one separate population; if these two populations overlap spatially, the groupings are probably also separate species.

Many of us therefore proposed a “genotypic cluster criterion” for species (Mallet, 1995; Feder, 1998). The term “genomic cluster” would perhaps be a more appropriate synonym in today’s postgenomic age. Species are recognized by morphological and genetic gaps between populations in a local area rather than by means of the phylogeny, cohesion, or reproductive isolation that are responsible for these gaps (Mallet, 1995). In a local area, separate species are recognized if there are several clusters separated by multilocus phenotypic or genotypic gaps. A single species (the null hypothesis) is recognized if there is only a single cluster in the frequency distribution of multilocus phenotypes and genotypes. The genotypic gaps may be entirely vacant, or they may contain low frequencies of intermediate genotypes, or hybrids (Figure 1). The definition is useful because one avoids tautological

thinking: hypotheses about speciation or phylogeny of taxa become independent of assumptions about the nature of reproductive isolation or phylogeny underlying the taxa studied.

Bayesian statistical procedures, called “assignment tests,” are today regularly used to estimate the numbers of genotypic clusters from individual multilocus genotype data (Pritchard *et al.*, 2000; Falush *et al.*, 2003; Huelsenbeck and Andolfatto, 2007); if such genetic clusters are statistically distinguishable in sympatry, most would agree that one is dealing with separate species.

Genotypic clusters are neither profound nor original; the author traces the earliest use of the method to Darwin’s (1859) morphological gap criterion of species (*see* Darwin’s Morphological Species Criterion), although earlier sources probably employ similar ideas since acceptance of evolution is not required to identify species on the basis of character distribution. Many similar proposals have been made more recently (Simpson, 1937; Hutchinson, 1968; Sokal and Crovello, 1970; Avise and Ball, 1990; Cohan, 1994; Smith, 1994). The approach is essentially the same in most taxonomic decisions (*see* Taxonomic Practice), in the phenetic concept (*see* Phenetic Species Concept), or in a practical application of the biological species concept (*see* below). Multilocus genotypic clusters are almost universally applied as a criterion of speciation in theoretical models of sympatric speciation (e.g., Dieckmann and Doebeli, 1999; Cavrilets and Waxman, 2002; Kondrashov and Mina, 1986; Kondrashov and Kondrashov, 1999): in these models, a bimodal genotypic distribution evolves via reproductive isolation, but it is the demonstration that a pair of genetically divergent groups of individuals emerge from a single population, rather than the mere existence of hybrid inviability or mate choice, that is required for evidence of speciation.

This general use of direct morphological or genetic criteria in the definition of species, as opposed to reproductive or phylogenetic inferences made from such data, has apparently lacked widespread support due to the supposed need for a separation between concept and taxonomic criterion (Mayr, 1970). The author’s intention was to justify the Darwinian and practical taxonomists’ species definition statistically and in terms of genetics, rather than to enforce, as in DNA barcoding, the use of genes instead of morphology to define species. Most genotypic cluster species can be recognized morphologically; for example, minor pattern elements in *Papilio* butterflies can be used to unite the various polymorphic forms; however, with abundant molecular marker data, we could easily use the genetic version of the criterion to sort actual specimens.

There is, of course, every reason to conclude after seeing a male butterfly mating with an unlike female that they belong to the same species. However, because hybridization does occur occasionally between forms normally thought of as different species, one is not so much using the mating behavior itself to define species as inferring that such matings are common enough to cause homogenization of gene frequencies between such males and females. We infer that, if we were to analyze their genomes, the two forms would have similar genetic characteristics apart from those few genes determining the polymorphism or sexual dimorphism, that is they would belong to the same genotypic cluster. Instead of reproductive compatibility being the primary criterion of species, as in the

Figure 1 Genotypic or genomic cluster criterion for species. A sample of individuals is made at a single place and time. Numbers of individuals are represented by the contours in multidimensional genotypic space. Peaks in the abundance are represented by “+.” Two species are detected if there are two peaks in the genotypic distribution (right, bimodal distribution; also see Jiggins and Mallet, 2000). Otherwise the null hypothesis of a single species is not rejected (left, unimodal distribution). Note: the axes represent multidimensional morphological/genotypic space, not geographic space.

biological species concept, we can turn the argument on its head and infer from limited data on reproductive compatibility that a single genotypic or genomic cluster is probable.

Asexual forms, unclassifiable under the interbreeding concept, and arbitrarily definable at any level under concepts depending on phylogeny, can be clustered and classified as a genotypic clusters in exactly the same way as sexual species. The precise taxonomic level of species clustering for asexuals is somewhat arbitrary, as in the phylogenetic concepts, but at least the method acknowledges this arbitrariness rather than purporting to use some higher evolutionary principle. Many asexual forms such as bdelloid rotifers have clearly distinguishable species taxa (Hutchinson, 1968; Fontaneto *et al.*, 2007), probably due to ecological selection for distinct characteristics. In bacteria, competition is thought to structure largely asexual populations with occasional promiscuous horizontal gene transfer into recognizable genetic clusters (Cohan, 1994, *also see* Ecological Species Concept). Thus, reproductive isolation may help but is not required for genotypic clustering.

Critics have argued that the genotypic cluster criterion in sexual species is nothing other than a gene flow concept of species under a different guise. This is true for one specialized interpretation of gene flow in sexual populations. If we define gene flow as successful or effective, as opposed to actual input of genes, we can see that a gene flow criterion becomes similar to the genotypic cluster criterion. To find whether a hybridization or gene flow event is successful, we must either follow the fate of every gene through all possible descendants for all time, or we may examine the genotypic state of a population and determine if genes from one form are mixed randomly with genes from another form. Looking for random associations of genes within genotypes in the genotypic cluster approach will be methodologically the same as a genotypic analysis to determine whether a population is interbreeding, but the latter requires additional assumptions. The genotypic cluster criterion in sexual species could thus be looked upon simply as a practical application of the biological species concept. However, one may prefer the genotypic cluster criterion to the interbreeding concept, if only because its name emphasizes that the definition is character-based, rather than actually based on interbreeding, and is thus applicable to asexuals as well as sexual species.

If a single geographic race, which previously intergraded at all its boundaries with other geographic races, were to split into two forms that coexist as separate genotypic clusters, we could have a situation where the original polytypic species became paraphyletic. The new species has been derived from only one of the component subspecies. Thus, paraphyly of species would have to be recognized as a possibility under this definition, as in both interbreeding and diagnostic concepts.

The Unreality of Species in Space and Time: Races Versus Species

Geographic races often form clusters differing at multiple loci from other races in the same species. The interbreeding concept or genotypic cluster criterion can be used to justify a classical polytypic species if the various geographic races meet at contact

zones that contain abundant intermediates (hybrid zones). We sample multilocus genotypes or phenotypes in local areas of overlap and determine whether a single peak (one species, i.e., abundant hybrids) or two peaks (two different species, i.e., rare hybrids) are evident in the local genotypic distribution (Figure 1). Hybridization may occur, but if it is so rare that character and genotypic distributions remain distinctly bimodal in zones of overlap, we usually classify them as separate species, even under the interbreeding concept.

Although this spatial extension of the local species is practical to apply to any pair of forms in contact, it is unlikely to lead to general agreement. The problem is that hybrid zones can be very narrow and may have separate forms that are highly distinct at multiple characters or loci, in spite of complete unimodal blending in local areas of overlap. Even adherents of the interbreeding concept are reluctant to lump such geographic forms within the same species. Examples include North American swallowtail butterflies (*Papilio glaucus*/*Papilio canadensis*; see Hagen *et al.*, 1991) and European toads (*Bombina bombina*/*Bombina variegata*; see Szymura, 1993).

An even worse problem is found in ring species, which form a continuous band of intergrading subspecies, but whose terminal taxa may be incompatible, and overlap without intergrading. Commonly cited examples are the herring gulls and lesser black-backed gulls (*Larus argentatus* complex; Mayr, 1970). Similarly, although most hybrid zones between European *Bombina* are unimodal, the same pair of taxa may have bimodal genotypic distributions in other zones of overlap (Szymura, 1993). Thus, geographic forms may be apparently conspecific in some areas, but overlap as separate species in other areas. Finally, if distinct populations are geographically isolated and there is no area of overlap, one cannot disprove the null hypothesis of same species under interbreeding or genotypic cluster criteria, but biologists are reluctant to unite such populations if they are very divergent. Laboratory hybridization could be tried, but many overlapping species are known to hybridize freely in captivity, while remaining separate in nature. There are good examples even in our closest relatives, the great apes, for instance the bonobo (*Pan paniscus*) versus the chimpanzee (*Pan troglodytes*), and among the gorillas (Uchida, 1996), but similar decisions must be made in almost any animal or plant group.

The problem of extending local species criteria spatially is due to the way in which spatially separated lineages diverge: time since population divergence is usually somewhat correlated with geographic distance. Paleontologists face a similar temporal problem when classifying fossils in different strata. Evolutionary rates may vary, but all lineages must ultimately be continuous, so there may be no very logical place to put a species boundary in time any more than there is in space. Paleontologists, like neontologists, use operational species on the basis of morphological gaps between taxa from the same and different time periods (Simpson, 1937; Smith, 1994).

These difficulties show why there is no easy way to tell whether related geographic or temporal forms belong to the same or different species. Species gaps can be verified only locally and at a single point in time. One is forced to admit that Darwin's insight is correct: any local reality or integrity of species is greatly reduced over large geographic ranges and time periods (*see* Mayr (1970) and Biodiversity in Space and Time).

The Importance of Species Concepts for Biodiversity and Conservation

Traditional: Species as Real Entities

Different species concepts seek to define species in mutually incompatible ways. Thus, a monophyletic species concept seems not very useful to evolutionary biologists because of difficulties with multiple gene genealogies and paraphyletic remnants. In contrast, the interbreeding concept and other concepts incorporating biological processes of species maintenance (e.g., recognition, ecological, evolutionary, and cohesion concepts) suffer in the eyes of phylogenetic systematists because they lack phylogenetic coherence and produce paraphyletic taxa, or worse. If we were to allow the basal unit of our taxonomy to incorporate paraphyly, it would be harder to justify a strict adherence to monophyly at other taxonomic levels. It is beyond the scope of this article to resolve these difficult issues, but these conceptual conflicts fuel the continued debate, and also highlight the fact that if species are indeed real, objective biological units, their unifying reality has been extremely difficult to verify.

Many ecological and biodiversity studies of actual organisms ignore these difficulties, and assume that species are objectively real basal units. Thus, in ecology, we have theories of global species diversity. In conservation, we have the Endangered Species Act in the US, which prescribes the conservation of threatened taxa we call as species. Populations not viewed as species, particularly putative hybrid taxa (like the red wolf, *Canis rufus*, of the southeast US), became seen as less valuable, even if rare. How do we recognize that a taxon is hybridized? Obviously, to be a hybrid, it must be a mere intergrade between two, real, objectively identifiable entities. The Endangered Species Act viewed species as important real conservation units and hybrids as unimportant. It did this because it incorporated the species concept in vogue at the time of its enactment, that is the biological species concept, in which hybridization is seen as an unnatural breakdown in isolating mechanisms (Mayr, 1970).

Alternatives: Genetic Differences More Valuable than Species Status

In 1990, the hybrid policy of the Endangered Species Act was rescinded. However, although some hybrid populations are eligible to be viewed as valuable in conservation, others, especially hybrids with invasive taxa can be a problem for conservation. In spite of much discussion, no replacement policy about hybrids has been forthcoming. There is undoubtedly a greater realization today that other levels in the taxonomic hierarchy are important elements of biodiversity. The diagnostic concept of species, while claiming to support the basal, objective nature of species, may be useful in that it encourages recognition of important biodiversity at a lower level than the interbreeding concept, in this case as subspecies within polytypic species. Conservation geneticists today often advocate the conservation importance of “evolutionary significant units,” “management units,” or “stocks” (a fisheries term) defined below the species level by means of various criteria along the continuum of genetic differentiation at

molecular markers (Moritz, 1994). But the reality of spatio-temporally extended species continues to elude us, and biodiversity in terms of numbers of species, including endangered species, remains difficult to measure. The author argues that this will always be the case. Because populations evolve, cohesion over large regions of space and time will continue to break down. If this is so, then it might seem best to adopt some other measure of conservation value that relies purely on the degree of genetic differentiation, for instance, at molecular genetic markers.

Species Differences as Ecologically Important Markers

However, there are many who would oppose using molecular divergence as a measure of biodiversity. Species of sexual macroorganisms within a local area such as a nature reserve are, for the most part, easily and objectively identifiable using morphology, behavior, genetics, or phylogeny. A pair of similar species normally must be ecologically distinct to co-exist. Sexual species will need some prezygotic isolation, so their mating behavior must also be different. Thus, counting species in a local area makes considerable ecological sense, and conserving species diversity in a local area would conserve actual ecological and behavioral diversity. Behavioral and morphological differences that differ among species seem more valuable evolutionarily, as well as having more interest to conservationists, than the probably mainly neutral differences at molecular genetic markers.

Biodiversity in Space and Time

As we have seen, this local view breaks down when we try to apply the term “species” over large areas or geological timescales. In some cases, there is an excellent homogeneity over large areas; for example, the painted lady butterfly (*Vanessa cardui*) and the barn owl (*Tyto alba*) have a virtually worldwide distribution and look similar everywhere. Other species are not so homogeneous: the familiar mallard (*Anas platyrhynchos*) group of ducks is as widespread, but has become highly differentiated into some 18 or so forms in far-flung outposts of the world. Exactly how many mallard populations are good species, and how many are races, or indeed, how many races there are in total, is a matter of taste. Current authorities recognize about 10 species, but there might easily be five or 15 in alternative treatments. One of the forms, the Mexican duck, *A. platyrhynchos diazi*, is threatened with hybridization by the true mallard, *A. platyrhynchos platyrhynchos*, which has been expanding from the north, and the American black duck (*Anas rubripes*) also hybridizes with the mallard, but appears to resist hybridization somewhat better than the Mexican form – hence its species status.

Faced with these difficulties, should we worry about whether or not we have a definite species when conserving endangered taxa over large areas? In the author's view, probably not, and criteria of distinctiveness, or ecological role should be more important on a case-by-case basis. Whatever one's answer to this question, it does not seem sensible to rely on a unitary spatiotemporal reality of species as a guide. We might conform to the current trend for taxonomic inflation, and

upgrade the Mexican duck to a separate species instead of a subspecies, but this should ideally have little effect on our view of its conservation value: this has led to no actual change in our knowledge of biological characteristics that affect conservation value. Most conservationists now agree that the former fetish for species-level legislation was a mistake. Conservation and legislation now generally recognize that living, evolving populations form fractal continua with species and genera over time and space, rather than attempting to rely on spurious fundamental units.

Species can still be fundamental units of local biodiversity, but they have this clarity only in a small zone of time and space, and so species counts become less and less meaningful as larger and larger areas are covered. Taxonomists might come to nominalistic agreements on a case-by-case basis, but even this shows little sign of happening yet. Ecological theory, as well as conservation and biodiversity studies must however recognize that species counts over large expanses of space and time represent only a sketchy measure of biodiversity, a measure that owes more to taxonomic and metaphysical fashion than to science. Yet conservation still depends on lists of endangered species at both local and global levels. It would seem necessary to have either a better way than species lists to estimate conservation value, or at the very least a more stable species criterion less prone to taxonomic inflation. However, it is the bleak truth that agreement on this matter has not yet been achieved.

A Brief History of Subspecific Taxonomy

Variation Below the Level of Species

Since the invention of binominal nomenclature by Linnaeus, there has been a conflict between “splitters” who named more or less well-defined local populations as separate species, and “lumpers” who ignored geographic variation, and united local variants into a single species. The problem was compounded by early systematists’ belief that species had an Aristotelian essence, each fundamentally different from similar essences underlying other species. To Linnaeus’ followers, it seemed important to decide, which level of variation was fundamental. The terms “genus” and “species” both result from Aristotelian philosophy, and although Linnaeus is usually credited with establishing the species as the basal taxonomic unit, he confused matters, after recognizing that some plant species were of hybrid origin, by suggesting that genera were a more important taxonomic level (i.e., a separately created kind) than species.

Once evolution was accepted, it became clear that variation at all levels in the taxonomic hierarchy was due to more or less similar causes; the only difference between variation above the level of genus or species and below was one of degree. Darwin realized that species could evolve from intraspecific varieties, and he used the term “species” in a new and nonessentialist sense: “... the complete absence, in a well-investigated region, of varieties linking together two closely allied forms, is probably the most important of all the criteria of their specific distinctness ... Geographical distribution is often brought into play unconsciously and sometimes consciously; so that forms living in two widely separated areas, in which most of the other inhabitants are specifically distinct, are themselves usually looked at as distinct; but in truth this affords no aid in distinguishing geographical races from the so-called good or true species” (Darwin, 1874). Using this criterion, Darwin classified all human races as members of the same species. Darwin showed convincingly that there was no essential difference between species and varieties; species were simply varieties, which had diverged more, and which could coexist without intermediates being common. However, with his term “varieties” Darwin did not clearly distinguish between polymorphic variants within populations and the identifiable geographic populations normally today considered as geographic races or subspecies. To Darwin the distinction was unimportant, because polymorphic variants, clinal variation, geographic races or subspecies, and good species formed a continuum. Darwin demonstrated that this continuum was excellent evidence for an evolutionary origin of the taxa we call species.

The Trinominal Revolution in Zoology

Many systematists wished to preserve the purity of the simple genus–species binominal nomenclature, but by the 1850s,

there were enormous stresses. It began to be realized that identifiable geographic replacement forms were an important intermediate stage between insignificant local variants and good species. Some lumped these replacement forms as varieties within species, whereas others continued describing these replacement forms as separate species: practices varied widely, leading to considerable confusion. Although some Europeans had long advocated naming marked geographic forms as subspecies, the accumulation of major North American museum collections during the great push of colonization and railway construction westwards was probably the most important catalyst of a revolutionary new systematics. In this new approach, nomenclature consisted of a trinomial: genus–species–subspecies, which is still the dominant taxonomic practice today. The maxim was: “intergradation (at the boundary between two geographic replacement forms) is the touchstone of trinomialism.” Examples from commonly observed birds, which intergrade are, in North America, the eastern rufous-sided towhee (*Pipilo erythrophthalmus erythrophthalmus*) replaced in the west by the spotted towhee (*Pipilo erythrophthalmus maculatus*), and in Europe the carrion crow (*Corvus corone corone*) found in the south and west, replaced by the hooded crow (*Corvus corone cornix*) in Italy, and the north and east of Europe. Among the ornithologists responsible for this revolution in North America was Elliott Coues, who published a catalog of American birds in 1872 incorporating an early version of this trinomial nomenclature, in which subspecies were prefixed by “var.” and Robert Ridgway, who finally dropped the “var.” in his own 1881 summary of North American bird nomenclature.

The American Ornithologists’ Union soon adopted this policy, and the idea then spread to Europe, particularly England where Walter Rothschild began amassing his vast collection of birds and butterflies, and had hired excellent and productive staff, the ornithologist Ernst Hartert and the entomologist Karl Jordan, to curate and describe the new material. Jordan was particularly important in spreading the idea of trinomial nomenclature to entomologists, and in promoting the abandonment of other subspecific nomenclature. He was regarded by the Rothschilds as the clever member of the staff (Rothschild, 1983), and published enormous systematic treatises as well as papers on the theory of systematics, justifying trinomial nomenclature and the recognition of the subspecies as a valid, identifiable taxon in its own right. Both Jordan and Hartert were Germans who contributed to and read European as well as English journals, and in Germany a similar revolution was taking place. Thus, these systematic ideas were able to spread to the rest of Europe in the time when science was often highly parochial. The standard trinomial nomenclature for subspecies, and the abandonment of other named ranks, such as semispecies and superspecies, soon became established in the International Code of Zoological Nomenclature, and has remained there ever since.

Meanwhile, botany, Linnaeus' major expertise, remained much less prescriptive. Many infraspecific ranks are still considered valid taxa under the International Code of Botanical Nomenclature. For instance, *Saxifraga aizoon* var. *aizoon* subvar. *brevifolia* f. *multicaulis* subf. *surculosa* is a valid scientific name in botany, with names for variety, subvariety, form, and subform as well as genus and species ranks. Cultivated strains, hybrids, subspecies, are also considered valid nomenclatural ranks in botany, whereas subspecies do not necessarily refer specifically to geographic populations, as is the case in zoology. The remainder of this article is concerned largely with zoological terminology. It is important to realize, however, that both the botanical and the zoological codes avoid controversy by not specifying how to decide whether a particular group of specimens is a species or infraspecific taxon. The goal of these codes is to merely regulate nomenclature once a decision of rank has been reached.

Theories of Divergence: Superspecies, Semispecies, and Subspecies

It is hard to imagine the diversity of ideas by which the systematists of 100 years ago explained geographic variation. At that time, evolution by natural selection was far from generally accepted, in fact many believed that it had been disproved. One of the most influential ornithologists of the time was Otto Kleinschmidt, who believed that all species suddenly came into being long ago, and since then had remained completely separate. Replacement forms or subspecies had diverged from the main species but, in Kleinschmidt's view, subspecies could never evolve into new species as the Darwinians supposed. To distinguish his new species concept from the older one in which geographical replacements might be named as separate species, Kleinschmidt called his theory of variation the *Formenkreis* (ring of forms) theory. The *Formenkreis* theory fitted neatly with, and indeed promoted the new practices of naming subspecies and trinomial nomenclature.

In those times many somewhat peculiar explanations competed to explain geographic variation and speciation, including Kleinschmidt's "nonspeciation" theory, Lotsy's hybridization theory, saltational evolution via mutation, inheritance of acquired characters, as well as natural selection. In Britain, Jordan and Rothschild argued eloquently and influentially against any new terminology (including *Formenkreis*) that had theoretical implications, and proposed incorporating as little evolutionary theory into taxonomy as possible, in view of the lack of agreement among scientists at the time. Rothschild and Jordan (1895, 1903), supported by Hartert, agreed both with the nomenclatural practice of naming subspecies, and also that subspecies were valid real taxa that could evolve into full species. They argued that the Linnaean term "species" should be retained for the whole group of races, and that the geographic races were not true species, they were simply subspecies or incipient species.

Others felt that the term species was too emotive to be used in the new, multiple-subspecies sense. Some scientists continued following the *Formenkreis* doctrine, and had begun to name quite distinct taxa, which did not intergrade at their boundaries, as subspecies. This situation led in the 1920s and

1930s to the neo-Darwinian ornithologist Bernhard Rensch scrapping the term *Formenkreis* because of its theoretical limitations, and instead substituting two new terms, *Rassenkreis* (circle of races) and *Artenkreis* (circle of species). *Rassenkreise* were again considered to be equivalent to species, composed of races or subspecies. However, now there was an additional layer in the taxonomy, of groups of *Rassenkreise* that replaced one another geographically, the *Artenkreise*. Thus an *Artenkreis* could consist of multiple *Rassenkreise*. Rensch and many others believed that the subspecies was an incipient species, of which the geographic replacement species, *Artenkreise* were a further development, until finally divergence was sufficient to allow complete geographic overlap, whereupon new *Rassenkreise* could again be formed.

These terms did not catch on, and most scientists came to the conclusion that the *Rassenkreise* were equivalent to the species taxa used by Linnaeus and Darwin. Probably a major reason that we do not use these multiple taxonomic terms in zoology is due to the prolific work published in English by another German, Ernst Mayr. Mayr had worked for Walter Rothschild, and knew Hartert. After Walter Rothschild was blackmailed by a lover, his enormous bird collection of 280,000 skins was sold in 1932 to the American Museum of Natural History, where Mayr happened to have been hired as a curator. Mayr's experience of ornithology, contact with the European literature, and burgeoning friendship with the geneticist Theodosius Dobzhansky (who convinced him of the lack of evidence for inheritance of acquired characters), lent a unique opportunity to influence the course of systematics and evolutionary biology. Mayr did not waste this opportunity. Mayr used ideas underlying Rensch's terms, but renamed them in English. The *Rassenkreis* became simply the species or polytypic species, with its geographic races being subspecies, whereas the *Artenkreis* became the superspecies, and its component parts semispecies, that is, replacement species, not very divergent but which may hybridize occasionally where they overlap. Mayr successfully blended the local species concept of Poulton and Dobzhansky based on interbreeding with the geographic *Rassenkreis* idea of species, incorporating Jordan and Rothschild's ideas about subspecies. He renamed this combination of ideas "the biological species concept," a term, which has since remained strongly associated with Mayr's name. His many influential articles and books promoted a new program of species study, a science of the species that is still with us today. Central to Mayr's system was the belief that discrete taxa such as species or subspecies would normally diverge in "allopatry," that is, in complete geographic isolation.

The Subspecies Today

Modern Views of Subspecies and Semispecies

The views of Darwin, Wallace, Rensch, and Mayr that geographic replacement forms, subspecies and semispecies, are in fact incipient species, has few critics today. Most geographic replacement species (i.e., semispecies, which intergrade only rarely when they meet) must indeed have evolved from previously interbreeding subspecies. Modern genetic data have done nothing to cast doubt on this idea. Meanwhile,

superspecies became a specialized term reserved for groups of semispecies that intergraded little at their boundaries. Because neither of these are valid ranks in the zoological or botanical codes, taxonomists normally name such replacement semispecies at the species rank.

Under the trinomial approach, taxonomists were now required to describe subspecies, which has been never seen as a particularly noble activity in comparison to the description of species, especially recently. A strong attack on the zoological subspecies was mounted by Wilson and Brown (1953). Both were systematists working on ants, a group particularly riddled with poorly conceived trinomials and other named varieties at the time. Wilson and Brown argued that subspecies rarely, if ever, could be justified on the basis of multiple characters, and that therefore they were not real taxa. The only real taxa were species, which in a sense were self-defining because interbreeding prevented divergent genes from flowing from one species to another. Subspecies that interbred at their boundaries, however, were not so endowed, so that genes and morphological characters could flow between them. Good examples of subspecies were put forward, which undoubtedly would be hard to justify on multiple character grounds. This single paper was enormously influential on systematics in the US, and generations of insect systematists trained at Harvard and Cornell, where Wilson and Brown worked, together with their own many intellectual descendants, and their students' students in turn, have eschewed the practice of naming subspecies.

However, recent work shows that many subspecies separated by hybrid zones do in fact differ at multiple morphological, behavioral, and genetic characters (Barton and Hewitt, 1985). For instance, the toad *Bombina bombina* meets its relative *Bombina variegata* across a broad front in Europe. The two forms hybridize freely in the contact zone – although the hybrids can be shown to suffer some inviability – and so should really be classified as members of the same species under polytypic or biological species concepts. However, it has always seemed natural to place such well-defined forms in separate species in spite of the fact they have not truly speciated. The two taxa differ strongly in call, morphology, skin thickness, the sizes of water bodies used for breeding, and egg size, as well as in mitochondrial DNA and protein sequences. The levels of differentiation suggest that the *Bombina* taxa have evolved separately for many millions of years. This situation of multiple character changes has now been shown to be true across many examples of subspecies as well as (semi-) species separated by hybrid zones. Effective gene flow can be shown to be almost completely blocked by hybrid zones such as these, even if hybridization is frequent (Barton and Hewitt, 1985). Thus, although some named subspecies undoubtedly merited Wilson and Brown's scorn, genetic evidence shows that there are plenty of local replacement forms, which hybridize at their boundaries but which do form real identifiable taxa that are not reproductively isolated, and are therefore valid subspecies under the Wilson and Brown criteria.

Subspecies, Species, and Conservation

This opposition among modern taxonomists to subspecies taxa can be traced as one catalyst of the recent diagnostic

version of the phylogenetic species concept. The adherents of this view of species, led by the ornithologist Cracraft (1989), proposed a radical species concept so that even a single fixed character difference may define a geographic form as a separate species. Multiple character justification is not considered necessary, even at the species level. The practical result of this new concept is that many local forms, having been downgraded to subspecies in polytypic species, are again being recognized as species, leading to taxonomic inflation (Isaac *et al.*, 2004). In birds and butterflies, which often have many morphologically or genetically distinct subspecies, this could easily result in a 2–10-fold increase in the number of species.

It is probable that the revision of geographic forms upward to the level of species is being driven not only by theoretical considerations, but also by existing conservation legislation, which proposes that endangered species are the valuable units to be conserved. If a reserve contains a taxon recognized as a species rather than just as a local subspecies, it may be seen as more valuable for conservation purposes. The potential consequences for biodiversity and conservation of the continued instability of the term "species" are detailed in the article Species, Concepts of. Today's conservationists are reducing emphasis on species conservation, and are becoming increasingly aware of biodiversity at all the levels of the hierarchy of life, including well-marked subspecies. Thus, the legislative need for differentiating local races as species may ultimately become less important provided that future legislation falls more into line with the prevailing biological thought.

Further Reading

Much of the historical overview in this article is covered by the excellent reviews of Stresemann (1936, 1975), Mayr (1982), and Rothschild (1983), as well as by other sources already cited. A recent biography of Karl Jordan (Johnson, 2003) and work on the connections between the species concepts of Darwin, Wallace, Poulton, Karl Jordan, and Ernst Mayr (Mallet, 2004a, b, 2008, 2009) may also be of interest.

Glossary

Character An attribute that is constantly distributed among all members of a species or a clade.

Homology Two structures hypothesized to share a common ancestry.

Homoplasy Similar attributes not due to common ancestry but rather to convergent evolution, reversals, or mistaken interpretation.

Macroevolution Evolution above the species level.

Microevolution Evolution within species.

Monophyletic group An ancestral species and all of its descendant species; evidenced by synapomorphy.

Synapomorphy Shared, derived similarity.

Three-taxon statement Two species (or taxa) are more closely related to one another than either are to a third; the most basic cladistic hypothesis.

Introduction

The terms taxonomy and systematics are frequently interchanged in common usage with little loss of meaning and they will be so treated here. Two accounts of the relationships between these terms exist, however. According to one, championed by neo-Darwinists Simpson (1961) and Mayr (1969), systematics encompasses broader studies of evolutionary relationships, whereas taxonomy narrowly concerns itself with classification and naming practices. Roy A. Crowson (1970), however, treated taxonomy as the broader field with the ultimate aim of phylogenetic classifications. Systematics, in this interpretation, is the narrower endeavor concerned with working out phylogenetic relationships in order to inform classifications (Wheeler, 2008, Introduction). Precisely defined, *systematics* (or systematic biology) is that subset of taxonomy concerned with delimitation of species and analysis of characters and cladistic relationships. *Taxonomy* is the broader field with the ultimate goal of a predictive phylogenetic classification and informative Linnaean names.

What is Systematics?

Systematic biology is a historical and comparative science providing a counterbalance to general or functional biology (Nelson and Platnick, 1981). As such, systematics is non-experimental, yet is based on rigorously testable hypotheses about homology, species status, and monophyly. Systematics is at once the most fundamental and inclusive of the biodiversity sciences: most fundamental because it discovers, describes, and makes identifiable species and provides the names by which all biological information is communicated; most inclusive because it ultimately gathers together, interprets in an historical evolutionary framework, and synthesizes all relevant evidence whether molecular, anatomical, ontogenetic, or fossil. Taxonomy is essential to the environmental sciences, but is itself more fundamentally an evolutionary science. Its theories are deeply rooted in concepts related to speciation, character transformation, and macro-evolution. Taxonomy uses insights from population genetics, geography, and ecology to understand species and their spatial distributions, and it provides a general conceptual framework within which

biological observations may be interpreted in an evolutionary framework.

Taxonomists focus on patterns of character distributions that distinguish species on the one hand and unite them into monophyletic groups on the other. Population biologists, in contradistinction, focus on the processes of speciation. These fields necessarily overlap at the species level but are fundamentally different in their theories, methods, and aims, the distinction aligning with that of pattern versus process (Eldredge and Cracraft, 1980). The boundary between population genetics and taxonomy was blurred in the early twentieth century by those who rejected studies of phylogeny as speculative and embraced exclusively experimental work below the species level, so-called “population thinking” (e.g., Mayr, 1942). This bias toward experimental research did much to increase the stature of genetics and unnecessarily and indefensibly decrease that of taxonomy. Interest in predictive classifications was renewed when taxonomists became early adopters of computer technology. Phenetics, at the time also called numerical taxonomy, posited that degree of similarity corresponds with community of descent. Pheneticists claimed to be more objective and endeavored to use all available data. It turned out that the results were repeatable, but only with the same algorithm and dataset. Further, the choice of algorithm was in itself subjective and it was ultimately concluded that such methods did not reliably retrieve evolutionary relationships. The next advance in theoretical systematics, arguably the most important advance since Darwin, was Hennig’s (1966) phylogenetic systematics. At last, taxonomic theories were explicitly testable.

Hennig reasoned that an infinite number of special purpose, artificial classifications were possible, each meeting the need of a small subgroup of biologists well but not generalizable to all situations. He recognized that life was so diverse that the only general classification system that is reasonably useful to all biologists must be based on the one thing that all life shares in common: evolutionary history. Phylogenetic classifications are optimally informative (Farris, 1979), facilitating both the retrieval of what is known about species and predictions about what is not. Formal Linnaean names associated with phylogenetic classifications have proven highly efficient communication tools and are integral to modern databases from GenBank to the Encyclopedia of Life.

Taxonomy is commonly misunderstood, largely because of its historical basis. Evolutionary history, not unlike the sequence of events in human history, is not replicable. The myriad circumstances and preconditions of ancestral species cannot be enumerated, much less recreated. Experiments are designed to control variables and to make predictions about one possible outcome among a universe of possible outcomes. Because history is a single sequence of events, no such universe exists. The tasks of systematics include the interpretation of the transformation of characters, recognition and description of species, and reconstruction of cladistic relationships — that is, the relative recency of common ancestry among species. The most unique aspects of taxonomic work include the following.

Historical perspective: Taxonomy is not infrequently viewed with suspicion because of its nonconformity to standard practices of experimental biology. There is a good reason for this: Taxonomy is not experimental. Phylogenetic history is unrepeatable; even if the clock could be turned back, it is unlikely that the course of events would be the same given the many contingencies of evolution (Gould, 1989). Fortunately, and unlike human history, evidence of phylogeny is preserved in the genome of organisms and the complex structures coded by genes. Taxonomy is no less scientific than experimental biology. However, it does require a different epistemology for its justification. Details of hypothesis testing in taxonomy will be discussed later in this section.

Comparative method: Taxonomy is comparative at virtually every level. Whether assessing variation within species, hypothesizing homology among characters, or choosing among several equally parsimonious cladograms, taxonomists are often comparing large numbers of specimens or species. No other subdiscipline of biology is comparative to the same degree.

Worldwide collections: This comparative aspect of taxonomy means that taxonomists must have access to specimens for every species of a group being studied, regardless of where on Earth these species might live. To make such work practical, taxonomists have assembled vast collections in major museums and herbaria. Although many biodiversity scientists need to study the same organisms or phenomena at the same study sites for extended periods of time, the same constraints do not exist for taxonomy. Just the opposite is true: Taxonomists require samples from the most disparate reaches of the geographic ranges of species and clades. To unambiguously sort out species, the taxonomist must see as much infra-specific variation as possible as well as study variation within closely related species. To complete as comprehensive a study of an entire group as possible, the taxonomist must examine every species possible within that group regardless of where or when they live or lived. This is a very different set of requirements than that facing the experimental biologist. Natural history collections are costly to assemble, laborious to maintain, and may only be accumulated with the combined efforts of many over very long periods of time. The great natural history collections of the world have been built up over a period of centuries and even the best of them contain but a fraction of all the world's species making international collaboration among scientists and curators essential.

Taxon inventories: Building taxonomic research collections demands that scientists with taxon-specific knowledge be encouraged and permitted to collect in as many locations within the range of their group as is possible. Long series of specimens are needed to address infra-specific variation. Two centuries of taxonomic practice has taught us that making species decisions in isolation, i.e., describing species based on material artificially restricted by geopolitical boundaries, leads to redundant species descriptions, synonymy, and taxonomic confusion.

Taxon scholars: Taxonomists are typically specialists and may spend their entire careers working on one or a few higher taxa. This is not surprising when it is recognized that a single genus or family may include hundreds or thousands of species. Also, good taxonomy requires a level of scholarship unmatched in experimental biology. A competent taxonomist must master all published literature in the taxon since 1758 (1753 for plants), learn all relevant anatomical terminology, understand the gathering, limitations and analysis of molecular, phylogenetic, and fossil data, know modern theories of species, characters, and phylogeny, learn to comply with a complex code of international rules governing botanical or zoological nomenclature, know their way equally well around field sites, museums, libraries, and laboratories, and master a range of technological tools. Taxonomist's scholarship is not bounded by geography, ecosystem, or even time: one must compare, interpret, and understand hundreds of characters across scores or hundreds of species at a time, constrained only by theories of monophyly.

Philosophy: In the philosophy of science, the demarcation principle draws the line between science and nonscience. To be scientific, claims of knowledge must be stated in such a way that further observation might show them to be false (Popper, 1968). Questions not open to critical empirical testing and possible rejection, such as "Is there a God?" are simply outside the limits of science. Stripped of the familiar trappings of experimental biology, how can the historical patterns constructed by taxonomists be scientific? Phylogenetic systematics finds epistemic justification in its hypothetico-deductive method (e.g., Gaffney, 1979). Knowledge does not exist with absolute certainty. Rather, "confidence" (in the common rather than statistical sense) increases in ideas in proportion to the number of times that they are subjected to, and survive, critical testing. The most rigorous scientific claims are the most vulnerable ones. For example, all-inclusive statements such as "all swans are white" are highly testable. Although observation of a million white swans cannot prove this claim about the world, seeing a single black swan is sufficient to show it to be false. Such all-or-nothing statements are in fact potentially falsified by a single observation.

An initial hypothesis can derive from anywhere — specific observations or merely conjecture, it does not matter. Hypotheses not founded on prior observations or based on few or poor observations, of course, are less likely to withstand critical testing. The point is that where a hypothesis comes from is secondary to whether it is formulated so as to be testable. From the initial hypothesis, generalizations and predictions are made about the natural world. Every member of a species, for example, is hypothesized to share a unique combination of characters. And a resolved cladogram predicts that

every character or species subsequently discovered will conform to the predicted pattern of relationships.

Cladistics or phylogenetic systematics seeks to reconstruct patterns of evolutionary history and to construct natural classifications. Darwin acknowledged the pioneering work on phylogenetic “trees” by Ernst Haeckel in Germany (Figure 1), but a century would pass before the theoretical advances were made that were necessary to make phylogenetics rigorous (Hennig, 1966). While frequently ignored, the technical distinction between a cladogram and a (phylogenetic) tree is a useful one (see Nelson and Platnick, 1981). A cladogram is merely a theory of the relative relationships among species: A and B are more closely related to one another than either is to C, for example. A tree, however, specifies common ancestors, whether named or hypothetical. Thus, a cladogram is more general and may be consistent with multiple trees.

Because it is easier to develop rigorous theories of cladograms than trees, taxonomists often emphasize the distinction between pattern and process. This is not to deny that evolution exists or is responsible for the cladistic patterns: the fact of evolution is a necessary and sufficient background assumption for doing cladistics. Nor does it imply that studies of processes in evolution cannot or should not be pursued. To the contrary, the cladogram assists in the interpretation of evolutionary processes by narrowing explanations to those consistent with an explicit chronology and process studies are a necessary complement to taxonomic studies.

In practice, it is very helpful to have a cladistic framework before interpreting evolutionary processes. And it is not coincidental that evidence of the relationships among species and their characters preceded and laid the groundwork for Darwin’s theory of evolution. Without a pattern of relationships, there is nothing for evolution to explain. It is noteworthy that some patterns of relationship have been recognized for a thousand years or more in spite of radically changing world views from creationism to modern evolutionary theory. Early classifications divided species into groups that had or lacked some property. Thus there were vertebrates and invertebrates. These have been described as “A” and “not-A” groups. “A” groups are defined based on a shared attribute (in our example backbone), while “not-A” groups are defined based on the absence of something. Given that cucumbers and racing bicycles also lack backbones, it is not surprising that groups like invertebrates generally prove to be artificial. The contemporary period of taxonomy may fairly be described as the concerted push to eliminate “not-A” groups and replace them with “A” groups.

The Evidential Basis of Taxonomy

Taxonomy is comparative and integrative, summarizing all attributes of species and higher taxa that are heritable, observable, and comparable as characters. For the taxonomist, a *character* is an attribute of a species or clade that is constantly distributed among all its members (Nixon and Wheeler, 1992). In the context of phylogeny, a synapomorphy (character) is shared by an ancestral species and its descendant species. A character is a theoretical construct and may occur in its original or in some subsequently modified form (Platnick,

1979). The character forelimb is shared among all quadrupeds, for example, irrespective of whether it appears as the arm of a man, the wing of a pterodactyl, or the flipper of a penguin. Similarly, a particular character “wing” (not homologous but analogous with structures by the same name in insects, bats, or pterodactyls) is shared by all birds, even when expressed as a flipper in penguins.

Attributes shown to be inconstantly distributed within a species are not characters, but traits. Traits are also known as polymorphisms and are the stuff of microevolutionary studies. Changing frequencies of alternative traits in populations provide crucial evidence of selection at work. Important for population genetics, the variability of traits makes them inappropriate for taxonomic studies at and above the level of species.

Any attribute that is heritable, constantly distributed within a species or clade, and differing between species or clades is a potential character. Character sources are not limited to, but include anatomy, embryology, paleontology, molecular genetics, biosynthetic pathways, and ethology. Hennig (1966) used the term *holomorphology* to express the totality of characters and emphasized that the source of characters is less important than how they are analyzed. Simple observations with a hand lens can be rigorously analyzed, while the most expensive sequence data can be rendered unreliable if improperly analyzed. “Total evidence” analyses are those that combine all available sources of data. An alternative practice is to exclude data perceived to be weak or incomplete and to map it onto a reconstructed cladogram.

Mature sciences often develop theories that are scientific (testable) yet not directly derived from observations possible with the senses. Subatomic physics is based on the existence of particles never seen by anyone, but these ideas have been shown to map precisely onto predicted outcomes in power plants and atomic bombs. In taxonomy, characters represent an intellectual tradition traceable to the idea of homology articulated by Richard Owen in 1842 and made consistent with evolutionary theory by Lankester in 1870, who differentiated homology from homoplasy (Nelson and Platnick, 1981). Even choices of what specimens to compare are relevant when a character may only be present at particular periods of the life cycle. Specimens at these character-bearing periods are called *semaphoronts*; thus, it may be necessary to compare only third-instar larvae or plants that have flowered in order to determine presence or absence of a character.

The availability of large amounts of DNA sequence data has added exciting new evidence for phylogenetic analysis that has both challenged and corroborated long-standing hypotheses (e.g., Hervé *et al.*, 2009). And as complete genomes are sequenced, molecular phylogenetic analyses are entering a new era of phylogenomics (Hervé *et al.*, 2005). As important as molecular evidence has become, it is not a panacea and is, as Hennig said, only as good as how it is analyzed. It is a common sense observation that as characters become more complex they store and convey more phylogenetic signal. A substitution of one nucleic acid for another at a single site along a strand of DNA is more easily replicated than the neck of a giraffe or even a complexly folded protein. We have only begun to deeply address the question “what is a character?” in the context of molecular evidence and some analytical

Figure 1 Treelike diagram depicting Ernst Haeckel's hypothesized phylogeny of life, cited for its genius by Charles Darwin.

methods of simple data appear to be throwbacks to phenetic rather than strictly phylogenetic analysis (Williams *et al.*, 2010).

Historical Context

The history of taxonomy is a long one, with roots lost in prehistory. Rudimentary taxonomy, it could be argued, is not unique to humans. Animals must distinguish food from foe in daily life, and mimicry complexes add further evidence of the observation powers of predators. The “Father of biological classification” is Aristotle who, in the third century BC, authored the first formal classifications. Aristotle’s ideas would shape biological thought for the next 1500 years. As Europe emerged from the Dark Ages, an interest in the medicinal uses of plants drove the compilation of *herbals* and renewed interest in classification. Cesalpino’s rudimentary species concept in *De Plantis Libri* was based on his observation that plant seeds gave rise to like kinds of plants was followed by John Ray’s idea of species in the mid seventeenth century that included most of the elements of modern species concepts. It is estimated by ethno-biologists that perhaps 50,000 species are used by humans around the world presently and it is not unfair to say that the growth of taxonomic knowledge is directly correlated with the rise of human civilization and continued improvement of human welfare.

The Swedish naturalist Carolus Linnaeus (Figure 2) is considered the “Father of Taxonomy” and initiated the systems of scientific names and classification that we use today. Linnaeus gave to us the now standard set of hierarchical

categories of classification: species, genus, family, order, class, phylum, and kingdom. The hierarchic nature of his categories, each more inclusive than the one below, proved preadapted for contemporary phylogenetic classifications, which are also hierarchic. He also devised Latin binominals as the names of species. The first word the genus name and the second the specific epithet. As the number of known species grew, this simple rule enabled us to use time and again descriptive and easily remembered epithets in multiple genera. Linnaeus knew and classified about 10,000 species in his lifetime. While this was a fitting achievement in his age of discovery, it also laid the foundation for the nearly two million species discovered and named since.

Comparative anatomical studies by Cuvier, Buffon, Lamarck, and Owen, among others, paved the way for the next major advance in taxonomy, evolution. It has often been claimed that Darwin’s theory had little impact on taxonomy, but this is ingenuous. That the good descriptive work that had been a necessary precursor to Darwin could continue to be done in largely the same way after Darwin does not suggest that taxonomists somehow missed the evolutionary revolution. To the contrary, taxonomists had already been grappling with explanations for the patterns of similarity seen in anatomical and fossil evidence and were quick to see evolution as the explanation they had sought for the patterns in their classifications. John Henry Comstock, the founder of Cornell’s entomology department, wrote in 1893 that “the description of a species, genus, family, or order, will be considered incomplete until its phylogeny has been determined so far as is possible with the data at hand.”

Figure 2 Prominent figures in history of taxonomy. (Left) Carolus Linnaeus (1707–1778), originator of modern classification and nomenclature, binominal nomenclature, and the hierarchic system of categorical ranks. He was also author of *Systema Naturae*, whose tenth edition in 1758 marks the beginning of recognized names for most animal taxa. (Right) Willi Hennig (1913–1976), originator of phylogenetic systematic or cladistic theory that realized Haeckel’s and Darwin’s vision a century earlier for classifications that reflect phylogeny through differentiation of synapomorphy and monophyly from related concepts. He was the author of *Grundzüge einer Theorie der Phylogenetischen Systematik* in 1950 and the highly influential *Phylogenetic Systematics* in 1966.

Although the goal of phylogenetic classification had become clear to post-Darwinian taxonomists, the method for achieving it remained enigmatic. The vacuum was soon filled instead with “evolutionary” or “eclectic” taxonomy that attempted to express both common ancestry and degree of divergence in classifications. Assumptions about evolutionary processes were speculative at best, and imposing degree of divergence on classifications led to another suite of problems. Many higher taxa corresponded to evolutionary grades rather than monophyletic clades.

In part, a reaction to the subjectivity of evolutionary taxonomy, phenetics, or numerical taxonomy developed putatively objective alternatives. The central claim of phenetics proved incorrect: Overall similarity did not reveal phylogenetic relationships. Rather than abandon phenetics, its practitioners admitted this failure and said instead that evolution was simply unknowable and that we should settle instead for objective, repeatable, artificial classifications. Many of the massive morphometric data sets compiled by pheneticists were subsequently shown to be suspect. Independence among their characters was questioned and in some studies the same ratios were clearly being measured over and over. More damning to phenetics, however, were two additional observations. First, their results were only repeatable given the same matrix (i.e., given no addition or subtraction of taxa or characters) and the same algorithm. By this time, there were scores of algorithms, any of which might give a different result from the next. Although each was “objective,” the choice among them was purely subjective. Second, J. S. Farris demonstrated in 1979 that the phylogenetic system was superior in information content, the very criterion used to promote phenetics. Farris had delivered a deathblow from which phenetics would never recover. Adding insult to injury, he successfully hijacked the phrase “numerical taxonomy” to apply to his parsimony-based phylogenetic algorithms.

Hennig’s 1950 *Grundzüge Einer Theorie der Phylogenetischen Systematik* had been read and cited by a handful of North American taxonomists, a few of which, such as Pedro Wygodzinski, had applied his principles. Almost immediately after the publication of Hennig’s *Phylogenetic Systematics* in 1966 (a new, English-language book), a theoretical revolution was afoot. Phylogenetic systematics developed rapidly along two parallel lines of scholarship that would converge years later. James S. Farris was transforming “numerical taxonomy” from the trivially objective phenetic methods to sophisticated computer-aided phylogenetic analysis. In so doing, Farris also laid the groundwork necessary to cope with massive numbers of characters that would later emerge from molecular sequence techniques. Simultaneously, Gareth Nelson, Norman Platnick, Eugene Gaffney, Donn Rosen, Joel Cracraft, E.O. Wiley, and other scientists associated primarily with the American Museum of Natural History were exploring the connection between the philosophy of science of Sir Karl Popper, Willi Hennig’s phylogenetic theory, and biogeographic work by Lars Brundin. The result was a powerful epistemic justification of Hennig and the transformation of cladistics to a rigorous science in its own right distanced from some of the evolutionary process assumptions common to taxonomic writings prior to Hennig and, to a lesser extent, inherent in Hennig’s writings.

Linnaean Nomenclature

There are, from time to time, proposals to abandon or replace the Linnaean system of scientific names. While the Linnaean system is not perfect and continues to be improved on, its fundamental effectiveness for managing and communicating taxonomic information is proven. The fact that the Linnaean system has been used continuously by zoologists since 1758 (and botanists since 1753) is not, of course, an accident or a slavish adherence to tradition. Pre-Darwinians recognized patterns evident in character distributions that were used by Linnaeus and his students to group “related” animals and plants together. For Linnaeus, these relationships were the result of choices of Creation, but regardless of the causal process assumed, the evidence was expressible in hierarchic form. As the evolutionary implications of such patterns of resemblance became clear (as, for e.g., to Haeckel, Lankester, and other nineteenth century biologists), improved explanations for the same undeniable patterns became available. Given a rigorous method for the study of phylogeny by Hennig, a classification system that was hierarchic in nature was a necessity to convey relationships. The Linnaean system, due to its hierarchic logical structure and nested ranks, ideally met this need.

Elements of Biodiversity

When biodiversity is viewed from a functional perspective it can be described in terms of a series of increasingly inclusive units from organism to populations, ecosystems, and ultimately the biosphere as a whole. Viewed from a taxonomic perspective, biodiversity is seen in an evolutionary hierarchy progressing from individual to species to series of increasingly inclusive higher taxa or clades. For a great many practical purposes, the species may be seen as the element of organization, whether as the least inclusive taxon in a phylogenetic classification or the kinds of microbes, plants, and animals interacting in ecological networks.

Consider two islands of equal size with ten species each. On one island are ten closely related species of a single insect genus. On the other island are one species each of ten higher taxa (i.e., one insect, one tree, one nematode, etc.). In one trivial sense, the islands have equal diversity with ten species each. In a different sense, the second island has more diversity. In measuring biodiversity of ecosystems and places, it is important to consider phylogenetic diversity as well as species numbers. Were all 20 of these hypothetical species unique endemics and we could save only one of the islands, the author suspects that most of us would find it an easy decision to favor phylogenetic diversity over homogeneity.

In recent years, several numerical indices have been proposed to account for biodiversity at and above the species level. When biodiversity is seen through the lens of taxonomy, in terms of both species and phylogenetic diversity, needs and priorities for research and conservation can appear very different. Combined with research results from ecology, population biology, migration ethology, and assessments of bio-economics and so-called biodiversity hot spots, these

Figure 3 Visualization of two competing hypotheses of the global distribution of biodiversity. (Right) The tropical model, based on a simple count of numbers of species, argues that most biodiversity is equatorial with decreasing levels toward either pole. (Left) The Platnick model takes into account both phylogenetic diversity and species diversity and suggests that most biodiversity exists in both the tropical and the southern temperate regions, resulting in a pear-shaped globe.

indices create a fact base for decision making in natural resource management and conservation biology.

Using the imagery of the world to represent broad-scale geographic models of biodiversity distribution, we can see three phases in the twentieth century. First was what Nelson and Platnick (1981) called the “Sherwin–Williams” model, with biodiversity originating in Northern Hemisphere centers of origin and species spilling southward in decreasing abundance. This traditional view was biased by many factors, including a focus on certain vertebrate taxa, but especially the location of major universities, museums, and herbaria in Europe and North America.

As tropical forests were explored in greater detail, it soon became obvious that there were large numbers of species at and near the equator. From this species counting exercise, a tropical biology mythology posited that the tropics are most diverse, with biodiversity levels diminishing latitudinally as one moves northward or southward. There are many taxa with enormous numbers of tropical species, and based on existing species counts the tropics unequivocally house more species than any other region in the world. This tropical view morphed the world into one with a much exaggerated equatorial region.

For many taxa, the southern hemisphere is significantly more species-rich than the northern. Further, when phylogenetic uniqueness is taken into account, there exist a disproportionate number of relictual clades found only in the far south. This suggests a radically alternative view of global biodiversity distribution that was described by Norman Platnick as pear-shaped, with most species found in the tropics and southern hemisphere and with diminishing numbers northward. This is the emerging view of biodiversity as a whole (Figure 3).

Given the many advances in population genetics, molecular genetics, and phylogenetic systematics, one might suspect we would have converged on one modern concept of species by now. Unfortunately, the twentieth century was marked by an increased number of competing definitions. This has been fueled partly by the confusion of the evidence and goals of population biology with that of taxonomy, beginning about 1940 (Wheeler, 2008, Introduction). Hennig (1966) was careful to articulate the distinction between what he termed tokogeny and phylogeny. Tokogeny has to do with birth relationships among individuals within a population or

Figure 4 “Line of death” depicting the significance of species in Hennig’s distinction between tokogeny or birth relationships (shared among individuals within and between populations of a single species) vs. phylogeny or patterns of relative recency of common ancestry shared among species. Hennig’s line – species – also corresponds with divisions between taxonomy and population biology, characters and traits, microevolution and macroevolution, and upward between species and higher taxa.

single species. Phylogeny, however, refers to relationships among *species*. Above this tokogenetic–phylogenetic line are phylogeny, macroevolution, and much of the subject matter of taxonomy. Below are population genetics, various stages of incomplete speciation, and the subject matter of population genetics. Species are at once the upper limit of the one science and the lower limit of the other. It is the importance of species to questions above and below this line that has contributed to friction and confusion over their definition (Figure 4).

Predictive Classifications

Cladistic hypotheses are expressed graphically as cladograms and in written form as phylogenetic classifications. Conventions exist by which the branching structure of the cladogram can be retrieved from a hierarchic list of taxon names, such as

phyletic sequencing (Schuh, 2000). Species are the least inclusive taxonomic category, although some authors recognize subspecies. In order that classifications and higher taxon names reflect the most recent ideas about phylogeny, they must be periodically revised.

In the interest of precision, Hennig (1966) introduced terminology that expressed the fundamental concepts in his theory. Monophyletic groups or clades include an ancestral species and all (and only) its descendant species. Paraphyletic groups are those that include an ancestral species and some, but not all, of its descendant species. Polyphyletic groups do not share a common ancestral species. Each kind of group can also be defined based on the evidence supporting it. Synapomorphies are shared derived characters (apomorphies or evolutionary novelties) and indicate monophyly. Symplelesiomorphies or shared primitive features used to group species result in paraphyly, that is, groups including some but not all descendant species. Errors in interpreting characters sometimes assert that independent characters are the same, leading to unrelated species being classified together polyphyletically. Instances of convergent evolution, parallelism, or reversal to ancestral states are collectively known as homoplasy (in contrast to similarity due to common ancestry, homology).

Figure 5 shows examples of such groups referring to a primitively flightless silverfish, a damselfly, a beetle, and a fly. The best available insect classification suggests that fly + beetle constitutes a monophyletic group whose sister-group is the damselfly. The silverfish is then sister to the other three combined. Were the silverfish and damselfly grouped together based on their comparatively simple metamorphosis, they would be paraphyletic because simple metamorphosis is a shared, primitive similarity in comparison to holometabolism. Were the small, aristate antennae of the damselfly and fly taken as similarity, the resulting group would be polyphyletic since it is based on convergent similarity and not on common ancestry. This example was used for simplicity. In practice, paraphyletic and polyphyletic groups involve a much broader scale of grouping errors.

Although Hennig's terminology has been applied below the species level, this is a questionable practice as it violates assumptions in his theory that explain why historical patterns are to be expected in phylogenetic systems and not in tokogenetic systems. Hennig's groupings were groupings of species (not individuals or populations) marked by completely transformed characters (not partially transformed ones). Hennig's method thus required recognizing species prior to cladistics analysis and thus granted special status to species.

Another trend is to insist that species be "monophyletic." Not only does this violate Hennig's original meaning of the term, it also imposes a constraint on species that is, at least in certain theoretical situations, untenable. Consider a widespread ancestral species from which a tiny peripheral population is isolated. If that isolate attains full species status, it may well be "monophyletic" but its ancestral species clearly is not. This kind of situation is potentially common enough to suggest that insistence on unique common ancestry within species is ill advised. In this hypothetical example, the ancestral species clearly does not cease to exist and the only derived characters that it possesses are shared also with the daughter

Figure 5 Example of Hennig's concepts of monophyly (based on synapomorphy), paraphyly (based on symplelesiomorphy), and polyphyly (based on homoplasy) illustrated by four hexapods: silverfish, damselfly, beetle, and fly. See text for discussion.

species. Such cases are not recognized as such in practice because the evidence would merely show a sister-group relationship between mother and daughter species. This is another example of why taxonomists work with general cladograms rather than specific phylogenetic trees: either the mother species in this instance has a unique apomorphy not yet discovered or it is the "paraphyletic" ancestor of the isolate species. Taxonomists leave it to other evolutionary biologists to speculate as to the particular processes behind this pattern.

We have already seen that many species concepts are presently in use. For many practical purposes, this is not in itself problematic. For others, however, it should be of great concern. In the absence of a uniformly applied species concept, certain fundamental comparisons become impossible. Are there more species in a comparable sized area of tundra or rain forest? Are there more species of moths or mammals?

These are critically important questions for conservationists and ecologists, but when dozens of species concepts are in use it is not at all clear what numbers to compare to find the answers. In the context of evolutionary biology it is interesting to seek explanations for why one lineage produces an order of magnitude more species over the same span of time as another. Again, unless the species counts are comparable, we cannot legitimately pose the question.

In zoology, the biological species concept gained nearly universal nominal acceptance during the middle of the twentieth century. The author says nominal because most textbooks and taxonomic publications claimed allegiance to the biological species concept, but very few ever gathered the data necessary to rigorously apply it. The biological concept was popularized by Mayr (1942) and others who advocated “population thinking” and is fundamentally tested by the ability to interbreed. Rosen (1979) tested the concept with freshwater fishes from Guatemala and demonstrated that the ability to interbreed is a shared-primitive condition and that the truly evolutionarily interesting phenomenon is the loss of the ability to interbreed. Botanists never found the biological species concept to be adequate for their needs, partly because of a greater frequency of hybridization among species. More recently, the biological concept has been attacked from several perspectives (cf. chapters in Wheeler and Meier, 2000) and there is growing support for the phylogenetic species concept.

Working simultaneously, two pairs of authors produced nearly identically worded versions of a phylogenetic species concept: Eldredge and Cracraft (1980) and Nelson and Plantick (1981). Their phylogenetic species concept is very similar to the morphological concepts in broad use by taxonomists before they were set aside in favor of the biological species concept, but it is formulated specifically in a phylogenetic framework. According to the phylogenetic species concept, a species is simply the smallest aggregation of (sexual) populations or (asexual) lineages diagnosable by a unique combination of character states. The argument has been made that the phylogenetic species concept is the unified species theory we have sought (Wheeler, 2010), but this is not yet a consensus view.

Debate continues regarding the best alternative. This battle over species concepts is far from a mere academic exercise (Table 1). Any effort to inventory or document biodiversity, to compare the biodiversity present in one habitat or geographic place versus another, and any wording in regulations aimed at natural resource management or biodiversity conservation will inevitably be described in terms of the numbers and kinds of species affected. Adopt the wrong concept, and we grossly

under- or over-estimate biodiversity with potentially catastrophic effects. It is important that this debate proceed with all due haste, but it is no less important that we arrive at the correct answer and not simply an expeditious or democratically popular one. Every student of biodiversity has a responsibility to consider this question carefully and fully and has a stake in the outcome.

The Missions of Systematics

Through a major initiative by the International Willi Hennig Society, the Society of Systematic Biologists, the American Society of Plant Taxonomists, and the Association of Systematics Collections, with funding from the U.S. National Science Foundation, the systematics community laid out a vision for the future of the field in the mid 1990s. Its visionary 1994 report, *Systematics Agenda 2000: Charting the Biosphere* (and parallel technical report), returned the focus of the systematics community to three traditional core missions that are energized by recent theoretical and technological advances and made urgent by the biodiversity crisis. Collectively, these missions address the most fundamental scientific questions about biodiversity (Cracraft, 2002).

Mission 1: To Discover, Describe, and Inventory Earth's Species

This mission seeks to answer several of the most fundamental of all biodiversity questions, such as “What and how many species exist?” “How are they related?” “What properties do they share with other species?” and “Where do they occur?” In slightly more than two centuries, taxonomists have documented nearly 2 million species (Chapman, 2009; IISE, 2012). An estimated ten million species of plants and animals (eukaryotes) remain to be discovered and described. Because few microbes (bacteria, archaea, etc.) can be cultured in the laboratory, our knowledge of their diversity lags behind. However, recent advances in metagenomics have allowed scientists to sample the DNA diversity of microbes directly from their environments. At the completion of the decadal survey of marine life, microbiologists speculated that the oceans alone may home to as many as 20 million microbial species.

Species exploration is on the threshold of a Renaissance as cyber-enabled taxonomy, or cybertaxonomy, comes into its own (Wheeler, 2004, 2008). Constraints of the past that were

Table 1 Alternative species concepts^a

Biological species concept (Mayr, 2000 p. 17): “groups of inter-breeding natural populations that are reproductively isolated from other such groups.”
Hennigian species concept (Meier and Willmann, 2000 p. 31): “reproductively isolated natural populations or groups of natural populations. They originate via the dissolution of the stem species in a speciation event and cease to exist through either extinction or speciation.”
Autapomorphic species concept (Mishler and Theriot, 2000 p. 44): “the least inclusive taxon recognized in a formal phylogenetic classification ... grouped into species because of evidence of monophyly” (see original for more extensive wording).
Evolutionary species concept (Wiley and Mayden, 2000, p. 73): “an entity composed of organisms that maintains its identity from other such entities through time and over space and that has its own independent evolutionary fate and historical tendencies.”
Phylogenetic species concept (Wheeler and Platnick, 2000, p. 58): “the smallest aggregation of (sexual) populations or (asexual) lineages diagnosable by a unique combination of character states.”

^aCitations from Wheeler and Meier (2000).

largely due to limited access to research resources are falling to the wayside one by one. The Global Biodiversity Information Facility has mobilized millions of museum records; the Biodiversity Heritage Library project is digitizing the natural history literature since 1758; the Encyclopedia of Life is building a Web page for every species; software to facilitate descriptive work is evolving rapidly toward electronic monography; institutions are busily populating digital archives with images of type and rare specimens; and remotely operable instruments are coming online that directly connect researcher and museum specimen. As cybertaxonomy flourishes in the decades ahead, the rate of species discovery and frequency with which species hypotheses are tested and improved will dramatically increase. And taxonomy will be increasingly democratized, closing a century's old gap between developed countries with great museums and libraries and developing nations with great species diversity, and removing obstacles to the quality of work achievable by motivated amateurs. Equally exciting is the facilitation of international cooperation among taxonomists and natural history museums. Recent Planetary Biodiversity Inventory projects (Knapp, 2008; Page, 2008) demonstrated the efficiency of teamwork in taxonomy and several strategies have been proposed to discover and describe 10 million species in no more than 50 years (Wheeler *et al.*, 2012).

Mission 2: To Analyze Phylogeny and Predictively Classify Species

Reconstruction of phylogeny is important to life science research in general and to predictive and maximally informative classifications in particular. All biological structures and functions can and should be seen in their historical (evolutionary) context. Phylogenetic classifications provide this conceptual framework that has proven instrumental to advances in fields as diverse as anatomy, behavior, and chemical ecology. Phylogenetic classifications allow us to efficiently store and retrieve what we know about biodiversity. Importantly, they also allow us to predict that we do not yet know. By virtue of knowledge of the biology of related species classified in the same genus, family, or kingdom, we can predict shared attributes of species not yet studied in detail. As we confront the exploration of tens of millions of additional species, such a predictive framework is essential.

Mission 3: To Disseminate Data, Information, and Knowledge

Cybertaxonomy is revolutionizing how taxonomic data, information, and knowledge are created, accessed, and used. The gold standard for taxonomic information remains the revision or monograph. Such studies comprehensively review and compare all available evidence, efficiently and simultaneously testing the validity of known species and describing new ones. In highly diverse taxa such as many flowering plants and insects, revisions were often completed only once or a few times each century. As research resources become available in digital form, it is possible to reconceive this process. In the future, it is likely that teams of specialists will collaborate to assemble and continually improve on comprehensive knowledge bases for

higher taxa that will fulfill the traditional role of the monograph. In any case, as a taxonomy-specific cyberinfrastructure matures, we can expect vastly more and more reliable taxonomic data, information, and resources.

Importance of Taxonomy

The biodiversity crisis (e.g., Wilson, 1992) has both increased the importance of taxonomic information and made the growth of taxonomic knowledge an urgent and high priority. How much farther can we push our understanding of the function of ecosystems without knowledge of what species exist and how they interact in complex webs? Without baseline data on what species exist and where, how can we hope to detect invasive species, shifts in floras and faunas in response to climate change, or losses of species diversity? And unless we explore, discover, and describe species now – expanding natural history museums and herbaria to document their diversity – we severely limit the detail with which we can continue to reconstruct and study the origin and diversification of life on our planet. The reasons that taxonomy is important to science and society include the following.

Conceptual Framework

Understanding the origin, organization, and function of the biosphere requires the input of many geological and biological disciplines from ecology to molecular genetics, population genetics, and phylogenetic systematics. While existing distributions and combinations of species are shaped by climate, physiography, soils, and competition, they cannot be fully understood without also understanding history. Many interactions and adaptations are constrained by phylogeny: a species can only function and change within the band of genetic information inherited from its ancestral species. A phylogenetic conceptual framework is a necessary complement to virtually any comparative question in the life sciences.

Language of Biodiversity

Formal botanical, zoological, and microbiological nomenclatures provide the language for communication about biodiversity. Although names never convey the full story of phylogeny, they are nonetheless powerful communication tools. If one beetle family, Staphylinidae, is mentioned, nearly two million species that are not rove beetles are immediately excluded... that is saying a lot. If two beetle families classified in the Staphylinoidea, say Leiodidae and Staphylinidae, are mentioned, it is known that the two families are related and share a common ancestry and the evolutionary novelties (synapomorphies) associated with it. We know from the “-idae” endings that the two are both ranked at the family level and therefore one is not included within the other. At the species level, the generic part of the binomial tells us something of relationships. And the specific epithet frequently tells us something about the species itself, often being descriptive of the organism (such as *Quercus rubra*, the red oak) or its origin (such as *Trechus appalachensis*, a ground beetle that lives in the Appalachian Mountains).

Although common names are not governed by enforceable rules, convention within taxonomic communities sometimes tells us useful information, too. For example, when entomologists use two words in a common name it usually points to one taxon while combined it points to others. For example, house flies, crane flies, and deer flies all belong to the order Diptera or true flies, whereas dragonflies, butterflies, and fireflies represent unrelated groups (Odonata, Lepidoptera, and Coleoptera, respectively).

Information Storage and Retrieval

Linnaean binomial species names have served as unique identifiers for species since 1758 and were easily adapted to serve the same purpose equally well in electronic information systems. Nearly every modern database from GenBank to the Encyclopedia of Life makes use of scientific names to organize, aggregate, and retrieve information. Innovative work on taxonomic indexing is expanding its role (Patterson *et al.*, 2005).

Evolutionary Record

The collections of specimens, tissue samples, DNA sequences, recordings, and other material evidence of biodiversity curated in natural history museums and botanical gardens around the world represents the most extensive and permanently useful record of the results of evolution. No action today in response to the biodiversity crisis is more important than exploring species diversity and preserving evidence of it in collections. We cannot anticipate where future curiosity and discoveries will lead us, but we can be assured that collections will remain a rich source of answers (NSTC, 2008). Our generation is the last that will have access to such a complete record of 3.8 billion years of evolution. Aiming to expand and develop collections as a comprehensive record of biological diversity at and above the species level should be a top priority for this century.

Environmental Baseline

Only by completing an inventory of earth's species can we create a baseline of environmental information sufficient to enable us to detect, monitor, measure, and adapt to biodiversity decline. Biodiversity sustainability is appropriately seen as a major goal for conservation biology and ethical land management, in large part to assure long-term ecological services. Unless basic taxonomic studies are completed, however, we will remain incapable of making fact-based environmental decisions and policies. Simply put, unless we know what kinds of plants, animals, and microbes exist in the first place, and where they are found in the biosphere, how can we hope to achieve biodiversity sustainability or even know if we have done so (Wheeler *et al.*, 2012)?

Biomimicry

The history of life on earth is written in innovative adaptations to selection pressures. Natural selection has, for nearly four billion years, undertaken rigorous trial-and-error experiments to find sustainable and effective solutions for survival and

problem-solving. Time and again, humans turn to biodiversity for ideas to solve our most pressing problems, and we are rarely disappointed. From antibiotics to sharkskin Olympic swimming suits, Mother Nature yields creative answers. Yet most such discoveries have relied on serendipity. A deliberate effort to mine biodiversity for answers, an emerging area called biomimicry (Benyus, 1997), is relatively new. As cybertaxonomy matures, one goal should be to create the shortest paths to promising answers. Among the most promising tools are species descriptions annotated to ease the retrieval of evolutionary novelties and phylogenetic classifications that allow the prediction of where to search for species with a particular property.

Glossary

Autapomorphy An advanced or derived character state unique to an individual taxon (of any rank).

Clade A complete ancestor–descendant lineage (cf., monophyletic group).

Cladogram A dendrogram expressing estimated cladistic relationships among taxa; a cladogram has no direct connotation of ancestry and the long axis does not connote time.

Dendrogram A branching, nonreticulate diagram expressing nested hierarchical relationships or similarities (or both) between entities (e.g., taxa) such that the entities only appear at the tips of terminal branches.

Diagnosis A set of attributes sufficient to define, characterize, or identify a given taxonomic group or separate it from others.

Grade A group based on, for example, the functional level of organization or overall similarity rather than ancestor–descendant relationships.

Monophyletic group A group comprising a given (hypothetical) ancestor and all its descendants; in a

restricted sense, within a given set of terminal taxa, all the members of a subset arising from a common ancestor that has given rise to no other member(s) of the entire set.

Paraphyletic group A group comprising a given (hypothetical) ancestor and only some of its descendants.

Phenogram A dendrogram expressing the overall similarity (long axis) between terminal taxa and sequentially linked groups of terminal taxa; the nodes do not connote specifiable characters and the long axis does not connote time.

Polythetic group A natural taxonomic group in which the terminal taxa are not known to share any universal unique character(s) but are nonetheless united by overall similarity (phenetics) or global parsimony (cladistics).

Sister groups Two terminal taxa or monophyletic groups that share a common ancestor that has not given rise to any other taxon under consideration.

Symplesiomorphy Character present in all subordinate taxa of a group under consideration.

Taxonomy is a highly controversial subject, and the issues are inextricably bound up with philosophical disputes that have endured for centuries. The problems are so important that no biologist can totally avoid facing them – Ghiselin (1969).

No one would think much of a chemist who confused water and benzene “because they look alike.” – Cain (1954).

Taxonomy plays the central role in the scientific discipline of systematics (Stuessy, 2009, p. 8), although, according to some authors (e.g., Schuh and Brower, 2009), the two are largely or even entirely synonymous. Systematics makes an essential contribution to our understanding of biological diversity, including its origins, distribution, and maintenance. The primary task of taxonomy is systematization: to establish and provide an account of biological order among the diversity of organisms. This involves enumerating the kinds of living things that exist and have existed in the past and

determining the patterns of difference and connection among them. By giving expression to these patterns through naming inclusive sets, subordinate sets, and the least included entities (e.g., higher classes, genera, species, subspecies, and varieties), taxonomists have produced the general reference system of biological classification: a categorical arrangement of named, diagnosable groups and components (taxa) that can be used to refer to all known living and extinct organisms.

Although effective taxonomy predates Darwinism, systematics is now closely linked to the theory of evolution. Descent with modification gives justification to the general form of classification adopted: hierarchical, non-overlapping sets rather than fuzzy sets or periodic tables. The fundamental methods of taxonomic systematization are few. Ultimately, there may prove to be only two – overall similarity methods (grouping by degree of genetic or phenetic similarity) and hierarchical methods (grouping by an inclusive phylogenetic or cladistic relationship) – but the theoretical bases of taxonomy are various. This has led to a proliferation of approaches, often

with variants. To understand alternative methods of taxonomy, it is necessary to appreciate the philosophical differences between these approaches, and much of this article is devoted to exploring these differences rather than describing techniques. The methods of cladistics, currently the dominant approach, are the subject of a separate review (*see See Also*).

The Tasks of Taxonomy

Taxonomists perform five main functions: discrimination (primary discovery or recognition of basic units of biological diversity in nature, notably species, also entailing a formal description and diagnosis of such taxa), systematization (by comparison, assessing the similarities, differences, and relationships among taxa), classification (production of summary schemes that encapsulate current knowledge of taxa and their main inter-relationships), symbolization (application of names to taxa and classes: technical nomenclature), and identification (secondary recognition of taxa: providing means to match unidentified material to the established system).

This article focuses on different approaches to primary discrimination and comparison of taxa (systematization) and the ways in which this knowledge can be expressed as summary schemes (classification). The procedures of taxonomy as an information retrieval system, which includes making checklists, catalogs, and databases, identification (naming specimens), and technical nomenclature (application and regulation of names: naming taxa), are not dealt with here. Nor, explicitly, are the means of gathering taxonomic data, for example, from anatomy, karyology, biochemistry, and nucleic acid chemistry, and their corresponding subdisciplines (morphotaxonomy, cytotaxonomy, chemotaxonomy, molecular systematics, etc.). Although such subdisciplines are often described as taxonomic methods, in the wider context of systematics and taxonomy as a whole, they are subsidiary techniques. Much the same methods and problems of interpretation apply, whatever the source of empirical data. This also applies to experimental taxonomy (the investigation of taxa based on predictions from alternative systems in an attempt to gather data bearing directly on particular taxonomic problems; *see the discussion in Stuessy, 2009, p. 20*) and morphometrics (quantitative comparison of related taxa based on continuously varying characters; *see, e.g., MacLeod and Forey, 2002*).

Disagreements regarding taxonomic methods can lead to major differences in classification. Such discrepancies range from disputes over the validity of species, subspecies, and infrasubspecifics at one end of the scale (*e.g., Funk and Omland, 2003*) to the extreme opposite, where the composition of even the most inclusive categories (domains and their component kingdoms) remains uncertain (*e.g., Foster et al., 2009*). By classifying the classifiers, it may be possible to identify some of the fundamental reasons, but not all taxonomic disagreements are due to the method alone because historical precedent and subjectivity still intervene. Moreover, in practice, a great deal of constructive taxonomic work is carried out with little reference to philosophy or explicit method, being achieved by pragmatic (empirical) intervention, notably the extension or modification of existing

parts of the system (*e.g., by description of new species and establishment of synonymy*).

Building Blocks: Individuals and Characters

Taxonomy is an empirical activity. On the basis of characters derived from sensory data, individual organisms or life cycles can be discriminated and then divided among or gathered into groups, and groups within groups, and so on to produce a taxonomic system. This can be done either top-down (divisive methods, as in Linnean divisions) or bottom-up (agglomerative, as in most phenetic clustering methods). Although individual organisms and characters are the basic elements in this process, their definitions are not straightforward.

Individual Organisms

Organisms multiply, typically from spores or fertilized eggs, to reproduce the corresponding parental stage through a cycle of growth and differentiation. At any point along such an ontogenetic pathway, a particular organism can be referred to as an individual: fertilized egg, embryo, larva, subadult, adult, or postreproductive adult. However, some organisms multiply by splitting or propagation, rendering the parent-offspring distinction uncertain. Thus, land plants can spread by runners so that what appears to be a field of separate individuals can be identical clones of one original plant. In the case of social organisms (*e.g., ants and termites*) in which very large numbers of workers, guards, or other castes may be produced that never have an opportunity to reproduce, the entire colony has some of the properties of an individual. These distinctions are important because the reliability of the taxonomic process, other factors being equal, is dependent on the number of individual organisms sampled as well as the number of characters recognized and recorded. Multiple sampling from essentially the same individual organism can distort our assessments of natural variation or the lack of it and lead to erroneous conclusions (*Wiens, 1999*).

Attributes and Characters

Taxonomists compare organisms by means of characters. Characters are abstractions derived from the detectable attributes of individual organisms or social groups (*e.g., consider "large, two curved unforked horns on head, two-color vision, herd with tails erect" as descriptive of wildebeest among mammals*). To be informative, it is obvious that characters observed must not be universal throughout the entire group of organisms under investigation. The distribution of characters is the primary interest, and the degree to which they differentiate, coincide, and conflict will largely determine their usefulness for taxonomy.

In general, characters can be divided into two sorts: continuous (*e.g., size, from large to small*) and discrete (*e.g., paired horns vs. no horns*). However, this is not absolute but more a matter of scale. Thus, different individuals of a particular kind of fly might bear every possible combination of 1–20 hairs on the thorax: is this continuous or discrete

variation? In addition, coding can be arbitrary (how large is “large?”) and subdivision can be ambiguous (MacLeod and Forey, 2002). If we observe different individuals with straight, curved, and forked horns, do we simply regard these as three separate characters, three states of one character (form of horn), or the intersection of two binary alternatives – horns straight/curved and horns simple/forked (with the expectation of being able to distinguish, in theory at least, two sorts of forked horns)? Moreover, there are other possibilities for coding such variables. The decision that authors make can affect the analysis (e.g., by encoding spurious information derived from inapplicable characters). Thus, if an animal lacks horns, and this is coded as three separate pieces of data (not forked, not curved, and not straight), such a redundancy can have undesirable effects on the analysis (Strong and Lipscomb, 1999).

In theory, unit characters must not only be nonredundant but also homologous and independent (Pimentel and Riggins, 1987). If different parts of the body are functionally interdependent or developmentally linked, it will be misleading to count these attributes as separate characters. This can occur when a single gene has a pleiotropic effect, influencing, for example, the color of one organ and the form of another. At the extreme, it is clear that multiple characters should not be created by logical correlation (e.g., treating both the circumference and the diameter of a circular organ as two unit characters). Some organs (e.g., parts of the male genitalia of insects) may appear so complex that counting them as one character seems unreasonable, but any stopping rule for subdivision may be uncertain, whereas other characters that appear simple may prove to be complex (e.g., a single functional bone formed by fusion during development, representing several characters in comparison with related taxa in which the equivalent bones have not fused).

Special and General Classifications

On the basis of characters held in common, individual organisms can be grouped into a large number of classes, which are of two general kinds. On the one hand, individuals can be grouped in terms of a particular attribute (e.g., green, round, four-legged, marine, planktonic, nocturnal, pollinating) or by small combinations of attributes to give prescriptions such as plankton-feeding marine organisms or nonflowering, epiphytic semiparasitic plants. On the other hand, they can be placed into categories of species, genera, families, orders, and so on. The former are regarded as artificial or special classes and are generally defined by reference to given attributes, whereas the latter are viewed, ideally, as natural kinds or natural groups that are discovered but cannot be defined *a priori* (although they can be diagnosed *a posteriori*).

Special classes frequently overlap, such as the overlay of plankton feeders, not all of which are marine, and marine organisms, not all of which feed on plankton, to define the special class plankton-feeding marine organisms; also, the same organism may recur in many different special classifications (e.g., eagle as flying organism, predator, or nest builder, and in the conjunction of all three). In contrast, natural groups typically form nested, nonoverlapping sets in

which each kind of organism or group appears only once. Thus, within the general classification of birds, all eagles are included as members of the family Accipitridae, which also includes vultures, buzzards, hawks, and kites.

Evolution, Genetic Relationships, and the Natural Hierarchy

Natural groups comprise individuals with many attributes in common, whereas individuals belonging to special classes have relatively few shared characters. In practice, the difference between, for example, large marine animals and Cetacea (whales and dolphins) is simply that individuals of the latter natural class have far more in common than those of the former. Even so, the word “natural” has had many connotations in the context of taxonomy, including the essence of things classified (Aristotle), rationality (e.g., as in God’s design), similarity, and explanatory power (Gilmour, 1940). Modern biology, however, has a unique theory that underpins its totality: the theory of organic evolution.

Ideas about evolution can be divided into a general theory of descent with modification and special theories about the processes affecting that descent (e.g., orthogenesis; natural, group, kin, sexual, and species selection; adaptive radiation; molecular drive; molecular clocks). Most systematists agree that the general theory of evolution not only provides a compelling justification for seeking one natural, general classification of living organisms but also suggests the basis on which this classification is most securely founded. A hierarchical pattern of exclusive sets and inclusive subsets can reflect the primarily divergent sequence of ancestor–descendant relationships.

Hennig (1966) used the term “tokogenetic” relationships for the reticulate genealogical links that occur between parents and offspring within an evolving, sexually reproducing population. When an entire population splits to form two or more divergent subsystems within each of which tokogenetic relationships are maintained but between which processes of genetic recombination are largely or entirely discontinued, speciation (or phylogenesis) occurs. If we describe two extant taxa as phylogenetically more closely related to each other than to any third taxon (regarding them as sister taxa), we imply that the two do not share tokogenetic relations now but did so in the past within a common ancestor that they do not share with any other living taxon. Such ideas were basic to Hennig’s concept of phylogenetic systematics. However, many organisms reproduce without genetic recombination (asexual) and thus lack tokogenetic relationships. Moreover, the huge variety of sexual processes suggests that tokogenetic relationships are not only nonuniversal but also may differ fundamentally in the many lineages where they do occur (Margulis and Sagan, 1984).

Species and other taxa grouped to reflect their phylogenetic relationships are expected, by virtue of their historical connections, to share far more characters in common than members of artificially formed groups. This expectation extends to unknown attributes, making phylogenetic classifications highly predictive. However, another type of genetic relationship is increasingly recognized as important in organic evolution: lateral gene transfer. The chimerical nature of

lichens as fungal/algal symbionts has long been recognized. Following the work of Margulis, it is accepted that at least two of the cellular organelles found in all eukaryotes originated through symbiosis of fundamentally separate organisms. Evidence is accumulating from molecular phylogenetics that the genomes of many major life-forms are chimeras formed from multiple original sources. The extent to which hybridization and lateral gene transfer undermines current approaches to natural classification is uncertain, but at least at the domain level, a nonreticulate hierarchy based exclusively on divergence appears to be unrealistic (Doolittle, 1999).

Differing Philosophies and Methods of Taxonomy

Taxonomic methods have developed over time. The massive edifice of taxonomic classification involving millions of terminal (e.g., species, varieties) and higher (e.g., phyla, families, genera) taxa, on which the scientific study, practical use, and conservation of biodiversity depends has been built up over centuries. This system has been produced by thousands of different minds using different methods, working with different knowledge, under different influences, and often seeking different goals. Some parts have been revised and reworked repeatedly and others hardly at all. To understand the strengths, weaknesses, and limitations of the current distributed taxonomic system, it is necessary to appreciate the ways in which systematists of contrasting persuasions have sought order in nature and tried to reflect that order in biological classification. In the sections that follow, the various approaches and methods are reviewed in a historical sequence.

Essentialism, Idealism, and Preevolutionary Taxonomy

In his early writings, it is clear that Linnaeus, the founding father of modern taxonomy, was trying to detect the pattern of Creation in the classes and species that he recognized and named. Linnaeus' system was, superficially at least, very simple. Having divided all life-forms into animals and plants, these kingdoms were then divided successively, on the basis of one or a few defining characters, into a series of smaller units down to the level of the genus (Linnaeus's genera were roughly equivalent to modern families, but the names he applied are nonetheless now deemed to be of genus rank). Within each of these genera, a large number of terminal species were usually recognized, and each was given a short, diagnostic description. For each species, Linnaeus also accepted that nameable variations could occur but considered that these did not represent the fundamental plan of God's work.

According to Hull (1965), Linnaeus started out as an essentialist, claiming that he belonged to an intellectual tradition founded on Aristotle's methods of logical division (Linnaeus later modified his views considerably). Aristotle was perhaps more concerned with the classification of our knowledge about living things, or even the generation of knowledge through the process of classification, than he was with the classification of organisms as such. The young Linnaeus was trying to discover or reveal deep knowledge: the natural order of God's Creation. Through his search for an external criterion

of verity, Linnaeus' concepts of species and higher taxa were fundamentally removed from those of the nominalists (*see* Nominalism).

Following Hull and Mayr, it has been argued that essentialism and related but distinct ideas of the early Greek philosophers, including Plato's idealism, have negatively influenced both the practice and the understanding of taxonomy. According to the typological species concept, every species was thought to have its own idealized plan or design. The task of the taxonomist was then to recognize each of these theoretical designs, and describe, divine, or define the essential features of these types so that individual, real organisms could then be assigned to them. Thus, for a Platonist, "taxonomic names are the names, not of organisms, but of concepts" (Ghiselin, 1969). Even today, many taxonomists consider given species as concepts (e.g., fulfilling some ideal as gene pools, potential interbreeding units, or mate recognition systems) rather than empirical entities that are discovered.

Idealism has influenced concepts regarding major groups of organisms, especially animal phyla, which many morphologists believed could be formulated as a series of fundamentally different body plans (ground plans or Baupläne). The notion of the ground plan was strongly developed by the ideal morphologists, who evidently affected some of the developing ideas of Hennig (*see* Phylogenetic Systematics and Cladistics) in the 1930s and 1940s, even though he flatly rejected their conclusions about the relationship between morphology and phylogenetics (Hennig, 1966, p. 11). According to Hull (1965), by supposedly ridding taxonomy of its essentialist and idealist burdens, and moving on to an empirical and relativistic evolutionary framework, Mayr, Hennig, and other modern systematists have liberated the science of taxonomy from a philosophical bind that held back progress for more than 2000 years. Hull's evaluation, however, has recently been challenged as based on no more than myth (Winsor, 2006; Schuh and Brower, 2009, p. 45). Moreover, Hull's supposed good news appears to be premature (*see* Conclusions).

Empirical and Inductive Taxonomic Methods

According to Mayr (1969), empiricism should be included as an atheoretical approach embracing the plausible, common-sense view that once sufficient knowledge has been gathered about organisms, a natural system of classification will simply emerge or become self-evident. Although it seems difficult to accord such a process the status of a general method, particular empirical observations can and often do render theoretical disputes irrelevant.

When Vaughan Thompson discovered in 1829 that barnacles develop from a nauplius larva, they were readily transferred from the Mollusca (where they had often been placed) to the Crustacea. Although this change in classification could in retrospect be justified by appeal to arguments about evolution, overall similarity, bauplans, or synapomorphies, to the empiricist, this would all appear unnecessary. To raise a brood of insects and find that all the males belong to one nominal genus and all the females to another leads to an instant appreciation of generic synonymy, without any need for appeal to theory.

The most complete expression of empirical classification occurs outside science in the form of folk taxonomy. Because folk taxonomy is well developed even in illiterate cultures, instead of inquiring into method or philosophy, it can only be understood by description and comparison. Berlin (1992) identified seven major features of ethnobiological categorization: recognition is given to the most distinctive local species; classification is based on affinities that humans observe (not on cultural significance); systems have a limited hierarchic structure; recognized taxa are distributed among a few mutually exclusive universal ranks, approximately equivalent to kingdom, life-form (e.g., plant), family, genus, species, and variety; in different ethnic systems, taxa at each rank show striking similarities regarding their number of subordinate taxa; taxa at generic and specific levels have an internal structure in which some included members are viewed as prototypical and others as reminiscent of other taxa at the same rank, giving rise to a type of fuzzy set classification; and a large majority of the taxa differentiated, most notably at the generic level, correspond to groups recognized in formal taxonomy.

These regularities and correspondences are highly suggestive of the fact that there is a natural biological classification that is almost literally self-evident and independent of the observer, and that a significant number of natural elements and groupings can be recognized simply through extensive knowledge and contact with nature. Although the young Linnaeus thought he was discovering the handiwork of God, it seems likely he was also involved in formalizing preexisting European ethnobiological knowledge.

Thus, as empirical knowledge accumulates, a common sense or consensus view of certain issues arises, and in some cases, such a view may seem irrefutable. Even so, there are many problems in taxonomy that cannot be decided (e.g., questions of relative rank or the status of paraphyletic groups) without an explicit theoretical framework.

Nominalism

One view of taxonomy is that, even though we may desire a general system, there are no independent means for assessment. The only objective realities are individual organisms and all taxonomic groups are man-made abstractions ("categories of thought" according to Louis Agassiz). Named groups are convenient for collective reference but have no independent basis separate from the human mind, simply being useful pigeonholes for dividing up or handling diversity. Many biologists have held similar views – apparently including Darwin, who once commented on species as a "term ... arbitrarily given for the sake of convenience to a set of individuals closely resembling each other" (see Mayr, 1963, p. 14; also Ghiselin, 1969).

By embracing the idea that taxonomic groups are established for convenience, nominalism has links with special classifications. If special classifications such as trees or four-footed land vertebrates are convenient, then there is no obvious reason why the nominalist should reject them, except insofar as it can be demonstrated that some comparable grouping has more heuristic or predictive power (e.g., trees

extended to Tracheophyta and literal Tetrapoda extended to include snakes, birds, whales, and bats); in other words, they are in some sense more convenient. Convenient for who then becomes the question.

Berlin's (1992) review suggests that folk taxonomies are not nominalist, which perhaps might have been expected, but seminatural and based on extensive empirical knowledge. Folk systems often have terms for conspicuous natural groups such as Mammalia, but it is not clear to what extent paraphyletic or even polyphyletic taxa are also included. Because folk taxonomies have terms for life-forms, which are in effect grades, this suggests that humans may possess an innate mixed strategy for classification, sometimes grouping on palpable characters, whereas at other times forming groups on the basis of general resemblance, Gestalt, or jizz.

Although Panchen (1992) suggests that there are no extant practitioners of nominalism, the view that species are real whereas all higher taxonomic groups are artificial is still quite widely expressed (even though quite misguided: contrast the difficulty of recognizing many species of mice with the ease with which the class Mammalia can be recognized by many consistent features; or the many dubious species of *Aster* recognized within the abundantly distinct Asteraceae: Stuessy, 2009). There are major disagreements regarding the existence of fundamental differences between terminal taxonomic components (e.g., species) and higher groups (e.g., polytypic genera and families), as accepted by Simpson (1961, p. 114) and Mayr Winsor (2006, p. 157), but rejected by Gilmour (1940) and Nelson (1989).

Evolutionary Systematics: Grades and Clades

The Darwinian revolution provided a rationale external to the human mind for the basis of taxonomy: hierarchical relationships among living things are explicable as the result of organic evolution, and taxonomists should strive to reflect these patterns as the logical basis of a general classification. However, if taxonomists looked to Darwin for a more detailed lead, what did they find? Unfortunately, at various places in the *Origin*, Darwin appeared to shift between general evolutionary statements ("the natural system is founded on descent with modification"), phylogenetic assertions ("the arrangement of groups within each class ... must be strictly genealogical in order to be natural"), and nominalism ("I look at the term species, as one arbitrarily given for the sake of convenience"). Moreover, the preevolutionary taxonomic hierarchy had served the Darwinians well, presaging a continuing debate to this day: is the theory of evolution relevant to the pursuit of taxonomy only as justification for seeking a single general system or should we build into the taxonomic method theories about the way in which evolution has occurred?

Whatever the precise reason, the immediate impact of Darwinism on method was very limited. Taxonomy remained highly individualistic, and idealist, nominalist, empiricist, and even creationist views all continued, although often cloaked in evolutionary language. The first move to formulate a general method post-Darwin did not occur until the 1920s, later epitomized by two books by Julian Huxley: *The New Systematics* (1940) and *Evolution: the Modern Synthesis* (1942). This

Figure 1 Evolutionary systematization. Horizontal axis, anagenesis; vertical axis, time. In this hypothetical case, the slope of each branch corresponds to the rate of anagenesis, with the percentage values representing the degrees of difference in the three lineages from the ancestral species (A). B is grouped with C because the two are more like their common ancestor than either is to D (even though D shares a common ancestor with C at X that it does not share with B). Note that this method requires a means of measuring similarity or distance (phenetics), estimating phylogenetic relationships (cladistics), and knowledge of ancestors (paleontology). Based on Mayr E (1974) *Gladistic analysis or cladistic classification?* *Zeitschrift für Zoologische Systematik und Evolutionsforschung* 12: 94–128, and Patterson C (1982) *Cladistics and classification.* *New Scientist* 29: 303–306.

emergent approach was developed and defended most notably by George Gaylord Simpson and Ernst Mayr, and it became evolutionary systematics or evolutionary taxonomy.

With respect to Darwin, the evolutionary systematists argued that the natural system (Figure 1) should reflect descent with modification, to include the processes by which evolutionary change occurs, the measurable degree of modification (anagenesis), and the temporal sequence of divergence (cladogenesis). According to Simpson (1961, p. 107), evolutionary systematics requires that a natural classification should be “consistent with all that can be learned of the phylogeny of the group classified,” but he was emphatic that this does not mean that natural classification be based on phylogenetic relationships alone – a view also clearly stated by Gilmour in *The New Systematics* (1940). This led Simpson to adopt a very broad notion of monophyly as “the derivation of a taxon through one or more lineages ... from one immediately ancestral taxon of the same or lower rank.”

To be natural, according to Mayr (1969), a classification must have explanatory, predictive, and practical values but also be emendable in the light of new evidence or understanding. Mayr then proposed that the fundamental basis for naturalness is the proportion or the number of genes held in common by any two taxa: “If we knew the entire genotype of each organism, it would be possible to undertake a grouping of species that would accurately reflect their ‘natural affinity’” (p. 81).

The empirical approach closest to this new ideal of evolutionary systematics is the use of pairwise distance data representing, in some way, the entire genome (e.g., immunological data and notably DNA–DNA hybridization data used

by Sibley and co-workers for bird classification). In addition, complete nucleotide sequences for the entire genomes of various organisms are now becoming available for direct comparison (e.g., *Chimpanzee Sequencing and Analysis Consortium*, 2005). These approaches, however, founder on some of the fundamental problems of phenetics. Mayr’s proposal that “genes-in-common” provides the ultimate arbiter of natural classification, however, is an important concept because it encapsulates the only well-articulated rival to the phylogenetic nexus idea first suggested by Darwin (“the arrangement of groups ... must be strictly genealogical in order to be natural”). If lateral gene transfer undermines a strictly hierarchical approach, then the estimation of genes-in-common will certainly increase in importance as the basis of a natural system.

In practice, evolutionary systematics became a syncretistic, all-embracing method that included a regard for the absence of characters as informative and insisted on the primacy of paleontology for revealing phylogenetic sequences (Figure 1). The method’s most striking characteristic involved conflation of the two methods that soon sought to replace it: a desire to give expression to genetic distances (grades or anagenesis, as reflected in phenetics) and, at the same time, to ancestor–descendant relationships (clades, or cladogenesis, as reflected in cladistics). Because these two methods stem from fundamentally different philosophies, this led to an inevitable arbitrariness (Figure 1). Thus, Simpson (1961, p. 107) was happy to write that although “taxonomy is a science ... its application to classification involves a great deal of human contrivance and ... there is a leeway for personal taste, even foibles.” This lack of explicitness led to the demise of evolutionary systematics as the leading method in taxonomy, although it still has some active proponents (e.g., Stuessy, who terms this approach “phyletic”). During its development, however, Mayr in particular made an enormous contribution, especially to ideas on the taxonomy of species, with which he was preoccupied as the basic unit of classification (Mayr, 1963, p. 11).

Phenetics and Operationalism

Phenetics (as numerical taxonomy) emerged in the late 1950s, its origin associated with, among others, Charles Michener, Arthur Cain, and especially Robert Sokal and Peter Sneath. In Sokal and Sneath’s (1963) *Principles of Numerical Taxonomy*, any evolutionary approach is avoided in favor of an operational method based on a direct comparison of phenotypes. As many characters as possible of the organisms to be compared, both continuous and discontinuous, are measured and counted from operational taxonomic units (OTUs), which can be individuals or samples of individuals from conventionally recognized taxa (typically species). On the basis of a matrix of variation in all features across all OTUs, the OTUs are then compared by overall similarity, affinity, or phenetic distance. Such measures can be obtained by transforming the raw matrix (Table 1) to yield the proportion of all character matches (affinity) or mismatches (distance: Table 2) for every pairwise combination of OTUs. The results are displayed by means of a network (Figure 2(a)) or OTUs are linked to each other by a clustering algorithm to produce a phenogram (Figure 2(b)).

Table 1 Amino acids found at eight particular positions in the myoglobin chain of four operational taxonomic units (OTUs): (A) Human, (B) Alligator, (C) Tuna fish, and (D) *Heterodontus* Shark^a

OUT	Characters							
	0	1	2	3	4	5	10	11
A	–	G	L	S	D	G	V	L
B	M	E	L	S	D	Q	V	L
C	–	–	–	–	–	A	V	L
D	–	–	–	–	–	T	V	N

^aSingle letters stand for particular amino acids and dashes for positions not represented, based on alignment of the four complete myoglobin sequences. Source: Reproduced from Patterson C (1980) *Cladistics. Biologist* 27: 234–240.

Table 2 Data of **Table 1** transformed into a distance matrix, based on the proportion of mismatches summed across all eight positions, for all six pairwise comparisons of the four OTUs^a

	A	B	C	D
A	0	0.375	0.625	0.75
B		0	0.75	0.875
C			0	0.25
D				0

^aThese distances are replicated in the branch lengths of an unrooted network (**Figure 2(a)**). Taken as reciprocals to give measures of similarity, the data can also be used to produce a phenogram (**Figure 2(b)**).

Although such a procedure appears objective at first, many different ways have been proposed to measure pairwise similarity or dissimilarity, and many different clustering methods have also been devised. Most clustering algorithms used in phenetics are sequential, agglomerative, hierarchic, and non-overlapping (SAHN). Among this class of methods there are subclasses (e.g., single linkage, complete linkage, and average linkage), which in turn have variations (Sneath and Sokal, 1973). The phenograms produced by SAHN algorithms are dendrograms and thus strictly hierarchical, lacking reticulations, appearing similar to a Linnaean hierarchy or a cladogram.

Initially, it was expected that an agreement would be reached on best if not ideal procedures, but this proved to be an illusion. As early as 1966, Hennig (p. 85) commented that “even the most recent authors present and recommend their own methods (for measuring morphological differences) but never explain why their method deserves preference over those of their predecessors.” Despite this difficulty, the pheneticists pursued their ideas with vigor based on four key hypotheses proposed by Sneath and Sokal that can be viewed as attempts to realize Mayr’s goal of measuring genes-in-common (Panchen, 1992, p. 135). The nexus hypothesis stated that every character is likely to be affected by more than one gene, and every active gene is likely to affect more than one character. The nonspecificity hypothesis suggested that no major or distinct group of genes would exclusively affect one class of attributes (e.g., morphology and behavior); thus, classifications based on one character class or set should not differ from classifications based on another class or set, and there would be no a priori reason to prefer particular data sets to

Figure 2 Phenetic systematization. (a) The values in **Table 2** between the four operational taxonomic units (OTUs) A–D represented by a distance network. The scaled lengths of the line segments are such that all the relative values in **Table 2** are satisfied, but the angles of the four branches leading to the terminals have no special meaning, (b) Horizontal axis, linkages; vertical axis, overall similarity. By taking reciprocals of the values in **Table 2**, the data yield a similarity matrix – the basis of a phenogram. With a value of 75% similarity, (C + D) are the first OTUs clustered. Comparing A with B, and (C + D) with A and B separately, (A + B) form the next most similar cluster, linked at 62.5% similarity. The two clusters can then be linked together at 37.5% similarity based on three of the eight attributes occurring in one or both members of the two groups. Other linking procedures could be adopted.

others. The hypothesis of the factor asymptote supposed that as data were added, the information content of the classification would reach an asymptote, whereas the hypothesis of the matches asymptote proposed that as the number of characters sampled increased, the similarity value for any pair of OTUs would tend toward a final, asymptotic value, thus conferring stability on the classificatory system.

Regrettably, for phenetics, as discussed by Panchen (1992) and even acknowledged by Sneath and Sokal as early as 1973, these hypotheses, apparently basic to the validity of the methods, are now largely discredited (in particular, the all-important nonspecificity hypothesis). More generally, phenetics offers no justification for choosing a hierarchical system unless it is accepted that the general theory of evolution dictates this as the most efficient representation. However, because phenetics conflates homologous and nonhomologous characters, and neither nodes nor branch lengths can be directly related to hypotheses about particular characters, the origin of characters, or even the degree of genetic change, the notion of overall similarity lacks analytical power.

Moreover, although it was originally expected that its procedures would lead to stability in classification, several

factors preclude this (Eldredge and Cracraft, 1980, p. 176). In addition to the technical ambiguities already noted, every new taxon requires complete reanalysis, with the unique attributes and combinations of attributes usually affecting every branch length and often many branching points in the phenogram. Of course, other taxonomic methods, including cladistics, are not invulnerable to change due to new discoveries, but in cladistic analyses, the effects are interesting (because they can be related to hypotheses about homology) and cladists never laid serious claim to the idea that stability in the face of new evidence was an important justification for the method.

Cladistics also has its own algorithmic problems, but it is always possible to work out what different procedures are doing with respect to the data and the inferences drawn. With phenetic methods, the nature of the algorithms and the form of the results are not separable. Thus, a basic problem of numerical phenetics is the lack of a clear criterion of choice (such as parsimony or even a model of evolution) by which one result can be judged against another (“the interpretation of evidence:” Schuh and Brower, 2009, p. 41). Even Mayr’s concept of genes-in-common will not repair the difficulty because of innumerable problems related to the definition of a gene, duplication, alignment, position effects, and so on. The only other external arbiter is the indefinable goal that James Farris called Gilmour-naturalness (“a system of classification is the more natural the more propositions can be made regarding its constituent classes”), enthusiastically embraced by Sneath and Sokal (1973). This led Panchen (1992) to suggest that the original philosophy of numerical phenetics is closer to empiricism (not nominalism, as suggested by Mayr). Given enough observations and an appropriate technique, the numerical taxonomists expected that a single, stable, and predictive general system would simply emerge.

Although phenetics has been judged wanting, it has had a lasting and positive influence on current taxonomic methods and still flourishes in areas such as bacterial taxonomy, where the general absence of tokogenetic relationships negates many advantages of a phylogenetic system. The most important contributions of phenetics have been technical, notably the use of data matrices, precise comparison across all taxa under scrutiny, and the adoption of algorithmic analytical methods. Advances in other methods, notably cladistics, have emerged not only from vigorous debate but also from the general adoption, post-Hennig, of data matrices and their exploration through other types of numerical algorithms.

Phylogenetic Systematics and Cladistics

The fundamental methods of phylogenetic systematics were established by Hennig, who wanted to base systematization and classification directly on the historical branching patterns of the phylogenetic nexus. He realized that it would never be possible to know the course of history precisely, and that the system would always be provisional. His goal was, by means of appropriate methods, to produce a phylogenetic system that would “approximate more closely than any other *the ideal system* (italics added) that reflects the phylogenetic relationships absolutely correctly” (Hennig, 1966, p. 29).

Table 3 Data from Table 1 transformed to show only coincidences of positive attributes among the four OTUs^a

Taxa	Character			
	2	3	4	11
A	*	*	*	*
B	*	*	*	*
C				*
D				

^aCharacters 2–4 link (A + B), and character (11) links (A + B + C). *denotes characters present. These data are most efficiently represented by the nested-set pattern (D(C(A + B))); compare with the pattern ((D + C)(A + B)) implied by the phenetic analysis (Figure 2). In this analysis, four characters (0, 1, 5, 10) in Table 1 are uninformative because there is no positive coincidence (5), only shared absence (0), both (1), or only shared coincidence (10).

Hennig’s method was the search for the sister group, epitomized as the three-taxon problem. For any group of three natural taxa, the expectation is that two have a common ancestor not shared by the third. Thus, for the trio shark, tuna, and human, of the three possible combinations of two from three, the one with tuna and human grouped to the exclusion of shark accords with what we know of ancestry (see Table 3). According to Hennig’s view, we should then recognize a taxon linking tuna and human as sister groups (Osteichthyes) but not one linking shark and tuna: from a phylogenetic perspective, Pisces (fish) are a paraphyletic or non-group. Thus, Hennig defined phylogenetic relationships solely in terms of common ancestry (propinquity of descent) and did not include similarity, distance, grade, adaptive zone, or any comparable concepts in his assessments.

This line of argument caused Mayr and other evolutionary systematists to object very strongly to Hennig’s approach, accusing him of an unjustifiable restriction of the concept of relationship. For this reason, Mayr referred to Hennig and his followers as cladists (from clade or cladogenesis) to criticize them for their narrow approach – with the unexpected result that the term was happily adopted by the growing band he sought to reprove (even to founding a journal with the title *Cladistics*).

However, how could clades be recognized in the absence of prior knowledge or without acceptance of sequences simply read from the fossil record? Arguably, Hennig’s greatest methodological advance was the introduction of relativism to the concept of characters. He recognized three classes with respect to a set of taxa under study: autapomorphies (characters unique to individual taxa), symplesiomorphies (characters present in all the taxa), and synapomorphies (characters shared by subsets of two or more taxa). According to Hennig, only characters of the third class provide evidence of grouping at the specified level of inclusiveness. Thus, a synapomorphy indicative of a natural group of species within the taxa under review (e.g., a genus) becomes a symplesiomorphy when addressing questions of relationship among species within that genus so delimited. Ideally, each and every character would be informative of relationships at just one level in the total hierarchy. Thus, virtually all the characters that might seem to unite shark and tuna to the exclusion of human (e.g., gills and fins) are actually characters that relate to more inclusive levels

Figure 3 Cladistic systematization. Horizontal axis, convention; nodes, pattern of homologous characters. The putative synapomorphies in **Table 3** plotted on all 15 possible arrangements (as fully resolved cladograms) for four terminal taxa. Numbers at given nodes indicate the shared attributes from **Table 3**; arrangement 11 is the only one that reflects all four attributes, all of which can then be construed as homologous characters. Based on Patterson C (1980) *Cladistics*. *Biologist* 27: 234–240.

of the hierarchy (e.g., Chordata and Vertebrata). Observations such as absence of mammary glands or absence of hair are not characters linking fish but the counter conditions of autapomorphies (of the Mammalia).

To see this in practice, the data in **Table 1** have been transformed (**Table 3**) to show only potential synapomorphies, i.e., the positive attributes shared by two or three of the four taxa, and thus able to provide evidence of grouping within (A–D). In this simple example, there are no conflicting distributions, and there is just one maximally efficient solution. Efficiency means the hierarchical arrangement that captures all (or, where there is conflict, the largest number) informative characters (putative synapomorphies). In **Figure 3**, all 15 possible fully resolved groupings of terminal taxa A–D are presented, with the characters that they can summarize marked at the relevant nodes. Arrangements 1–7, 9, 14, and 15 do not reflect any of the characters. Arrangements 10 and 12 capture one, and 8 and 13 capture three, but only arrangement 11 captures all four. The best cladistic arrangement, on the available data, is therefore (((A + B)C)D).

Patterson (1980) summarized the axioms of cladistics as homologous characters having a hierarchical pattern in nature in which this pattern is efficiently expressed by cladograms, with the nodes connoting homologies shared by the organisms so grouped. The search for the sister group therefore reduces to finding the cladogram that summarizes the potentially homologous characters as parsimoniously as possible. Once this best-fit cladogram has been found, the attributes at each node are hypothesized as homologous characters shared by the taxa subtended at that node.

One of the most challenging features of cladistics (or at least transformed cladistics – see Current Practice: Variations

Table 4 Imaginary character matrix for four taxa and six characters^a

Taxa	Character					
	2	3	4	11	x	y
A	*	*	*	*		
B	*	*	*	*		
C				*	*	*
D					*	*

^aCharacters 2–4 and 11 correspond to **Table 3**. *denotes characters present. Additional characters x and y are in conflict with character 11. The most parsimonious solution, assuming that all characters are independent, is to group the four taxa as ((A + B)(C + D)). This implies that attribute 11 is no longer considered homologous (not the same in C as in (A + B)) or that it is symplesiomorphic with respect to the entire group (A + B + C + D) and does not appear in taxon D (e.g., in evolutionary terms, this would imply that character 11 had been secondarily lost in taxon D).

on a Cladistic Theme) is the link between attributes, grouping, parsimony, characters, and homology. An attribute is accepted as a character if the weight of evidence from all other attributes under scrutiny suggests that it is a homologous feature peculiar to a particular group. In **Table 4**, two potential synapomorphies (x and y) have been added to the distribution of characters in **Table 3**. Given these additional data, and presupposing the independence of all the attributes, the most efficient grouping of the four taxa based on positive shared features now changes and highlights a problem with the interpretation of attribute 11: either it is not relevant as a character within the group and has undergone reversal in taxon D or it is not a character at all (it is nonhomologous).

Information about this could be sought, for example, by studying the ontogeny or some more fundamental quality of attribute 11 in A–C, revealing a particular scientific strength of the cladistic method: conflicts can be resolved by character analysis (Kitching *et al.*, 1998) involving recourse to additional data derived from previously unsampled or unused attributes or by investigation into the homology of the conflicting characters (they are not simply aggregated at face value, as in phenetics).

If characters x and y in Table 4 were found to be due to the pleiotropic effects of a single gene, then rejection of attribute 11 as a character relevant to resolving the relationships within the group would be premature. If, however, character 11 was a certain color produced, for example, by a pigment shared by taxa A and B, but the same hue was produced by a totally different type of pigment in taxon C, this would be consistent with the idea that attribute 11 as originally formulated (color) was a noncharacter. The similarities and differences between taxa A and C in this regard should then be rescored as two new attributes (e.g., based on chemistry), lending further support to the (A + B) grouping and removing conflict with the (C + D) grouping. The convergence in color between (A + B) and C could then be seen to be in the eye of the human observer. Such convergences are of intense interest for the study of evolution, but once detected, they play no part in the process of natural classification.

Thus, the relativistic nature of cladistics is emphasized. Based on the entire (attribute × taxon) matrix, the cladograms chosen and attributes thereby specified as homologous characters are probability statements: “Common ancestry versus convergence is tested by topographical correspondence (on the cladogram). The resulting explanation is a statement of maximal likelihood rather than a denotation of lawful relations or processes” (Rieppel, 1988, p. 166; see Hennig, 1966, p. 29).

General Procedures

The main operations involved in taxonomic research are listed as follows in an idealized order. In practice, this order is rarely followed precisely, and certain steps may be omitted in part or even altogether:

1. Individual specimens, or individuals representing selected taxa (ideally at least all immediately subordinate taxa currently recognized within the group under study), including material representing suitable outgroups for comparison, are chosen.
2. A selection of attributes to be scored across all samples of taxa under study is made (in original work, this will usually be a mixture of known and novel features).
3. The manifestations of these attributes are systematically recorded in an individual or a taxon/attribute data matrix (in the process of doing this, it is normal for other potentially informative features to be recognized and these may be added to the list under stage 2; it is not unusual at this stage for additional study material also to be called for, when variation has become apparent or specimens prove to be incomplete or otherwise unsuitable).

4. Systematization of the data is carried out by cladistic analysis to produce a cladogram based on homologous characters defining each node (or, for phenetic analysis, by an agglomerative numerical technique to produce a phenogram); in cladistic studies, this may involve one or more rounds of Hennigian reciprocal illumination, notably with respect to testing the coherence of putative homologies that seem to be in conflict (incongruent).
5. Inclusive monophyletic groups inferred from the parsimonious distribution of homologous characters are thus linked together and then named as taxa, to produce a hierarchical classification.
6. The homologous characters are used to help develop diagnoses for the various taxa recognized (as a potential aid for identification, information on characters that are absent may also be included, and keys, tables, or computerized identification programs may also be constructed at this point).
7. Publication of the results will ideally include the provision of necessary descriptions, indications (diagnoses), specifications of type specimens, and formulation of names in accordance with the relevant code (e.g., zoological, botanical, and bacteriological codes) as well as a record of the complete character matrix and specification of the analytical procedures used (e.g., computer programs and options and models in the case of maximum likelihood analyses).

Cladistic and numerical phenetic methods are essentially the same up to stage 3, but a crucial difference occurs at stage 4, the process of systematization. Stages 5 and 6 also differ, but both methods involve some arbitrariness with respect to where the phylogenetic nexus is to be cut or the phenogram to be divided (*see* From System to Classification). At stage 6, there is also some difference in that the very act of cladistic analysis gives the primary characters for diagnosis, whereas the numericist is faced with an additional searching process to enumerate a sufficient set (usually a polythetic set) of characters, whereby given members of a specified portion of the phenogram can be recognized in isolation. Fundamental differences in approaches to systematization have already been discussed (*see* Differing Philosophies and Methods of Taxonomy). The problems inherent in stage 5 are discussed next.

From System to Classification

Classification involves translating a systematization scheme into words (or numbers). Based on the methods of logical division, Linnaeus (who established many of the conventions of formal classification) placed all known organisms within a descending series of fully nested hierarchical categories. The major ranks in the Linnean system were kingdom (e.g., plants and animals), class (e.g., Mammalia, Aves, Pisces, and Insecta), order (e.g., Hemiptera, Lepidoptera, Coleoptera, and Diptera), genus (e.g., *Culex*, *Tipula*, and *Musca*), and species (e.g., *Musca domestica* (housefly) and *Musca vomitoria* (bluebottle)). For Linnaeus, systematization and classification were the same. Modern classifications attempt to summarize far more complex schemes. In this brief review, only the major differences between the major twentieth-century methods are considered.

Figure 4 Evolutionary classification. The original caption reads: “Three hypothetical phylogenies ... divided into taxa as shown by the broken lines. A is evidently less arbitrary ... than B, and B somewhat less than C.” Redrawn from Figure 7 in Simpson GG (1961) *Principles of Animal Taxonomy*. New York: Columbia University Press.

According to the evolutionary method, classification should be viewed as a useful art, meaning that in addition to scientific analysis, human ingenuity is also needed to produce a practical classification. Simpson (1961) recognized three principles: a classification should reflect the most biologically significant relationships among the organisms, it should be consistent with the relationships on which it is based, and it should be as stable as possible without contravening the first two principles. These ideas were elaborated to include, most notably, grades and clades (anagenesis and cladogenesis), both of which were regarded as significant for classification. This led to the idea that, even if literally everything relevant were known about the connections among the members of a group, “innumerable different classifications could be made consistent with those interrelationships ... Selection among those alternatives is decidedly an art” (Simpson, 1961, p. 110).

To appreciate the difficulties resulting from such a view, consider Figure 4. In cladistic terms, three paraphyletic groups (basal groups in A–C) are delimited, together with just four of the 34 subclades depicted. Why were these particular groupings chosen? Such a mysterious art proved difficult to follow (especially when the prescription for creating such trees in the first place is also imprecise). As discussed previously (see *Evolutionary Systematics: Grades and Clades*), Mayr urged that classifications be based on genes-in-common. Because it is a distance method, this transformation in evolutionary systematics encounters the same problems of classification faced by phenetics. Recently, the demonstration that the human and chimpanzee genomes are extremely similar (Chimpanzee Sequencing and Analysis Consortium, 2005) has led many mammalogists and primatologists to abandon the paraphyletic or grade family Pongidae in favor of an expanded and strictly monophyletic Hominidae, thus abandoning the position adopted for decades by the evolutionary systematists, who argued repeatedly that the large gap between *Homo* and the rest of the great apes was reason enough to place them in separate families (Simpson, 1961; Mayr, 1963). Even so, in this particular case and despite the small genetic or genomic distance, the highly autapomorphic nature of the human condition continues to give rise in some to misgivings about classifying *Homo sapiens* as just another ape (Guldborg, 2010) whereas, more generally, a few taxonomists continue to call for the formal recognition of paraphyletic groupings (e.g., Hörandl and Stuessy, 2010).

Figure 5 Phenetic classification. The formation of phenons from a phenogram. Redrawn from Figure 5.33 in Sneath PHA and Sokal RR (1973) *Numerical Taxonomy: The Principles and Practice of Numerical Classification*. San Francisco: Freeman.

Sneath and Sokal (1973) proposed that good classifications have three desirable properties: naturalness, ease of manipulation, and practicality for information retrieval. Their concept of naturalness, as already discussed, was based on the ideal of incorporating all codified information about a very large numbers of characters. Manipulation related to the practical relationship between a classification and its degree of hierarchical structure (useful for memorizing) and its utility (e.g., for the construction of identification keys). Convenience for information retrieval was also viewed as important, but not if it conflicted with natural classification.

The typical product of systematization by phenetic methods is the phenogram (Schuh and Brower, 2009, p. 12). How is such a dendrogram turned into a summary classification of named groups? An early proposal was the use of phenon lines (Figure 5). A phenon line cuts across the phenogram at a particular similarity level. The lines must be straight and are not allowed to “bend up and down according to ... whim” (Sneath and Sokal, 1973), not only delimiting groups but also determining their rank. Thus, in Figure 5, if OTUs 1–10 are species, the 80% phenon line could indicate seven subgenera, the 75% line four genera, the 65% line three subfamilies, and so on.

Such a procedure is not objective. The most fundamental problem is simply that the choices of percentage similarity levels and ranks are arbitrary, both within groups and between them. Other procedures, such as McNeill’s method based on the assignation of rank levels to each node, also involve arbitrary limits and adjustments. The difficulty for phenetics is

Figure 6 Cladistic classification. Labeled cladogram of the main lineages of the order Lepidoptera (slightly modified from Scoble (1992), Figure 185). In this classification, two of the major monophyletic groups recognized are not named (X) and the ranks of the terminals are noncoordinate. The dashed line to the Lophocoronoidea indicates that the relationships of this group are uncertain: they may form the sister group of the Exoporia, the Neolepidoptera, or the Myoglossata (Scoble, p. 203). Noncoordinate terminals and unnamed major lineages also appear in a recent phylogenetic scheme for the Ditrysia. Reproduced from Figure 3 in Regier JC, Zwick A, Cummings MP, *et al.* (2009) Toward reconstructing the evolution of advanced moths and butterflies (Lepidoptera: Ditrysia): An initial molecular study. *BMC Evolutionary Biology* 9: 280. doi:10.1186/1471-2148-9-280.

that “there is no necessary structural relationship between the pattern of clusters in hyperspace and the inclusive Linnean hierarchy into which they are converted” (Panchen, 1992, p. 151). If this is so, then there can be no nonarbitrary method for converting a phenogram (or any other distance-based method of systematization, including DNA–DNA hybridization trees) into a ranked summary classification.

Cladistic classification is based on the tenet that every putative monophyletic group can be named, but polyphyletic and paraphyletic groups should not. In a grand, top-down cladistic classification of all life, all coordinate monophyletic taxa (sister groups) could be placed at the same rank. Alternatively, taxa of the same geological age could be given the same rank (Hennig, 1966). Or classifications could be formed bottom upwards by linking all terminal sister species starting with the lowest-ranking pair or pairs and building up classes and ranks based on sister groups and ascending ranks held coordinate across the entire hierarchy. Such grand visions remain almost wholly impractical due to our very imperfect knowledge. Moreover, such systems would cause massive proliferation of named groups and ranks and be unstable in the face of most newly discovered taxa and every older geological find. In terms of producing a useful summary, cladistic classification thus faces potential problems of impracticality as well as arbitrariness.

In practice, when classifications are based on cladograms an attempt is usually made, within conventional ranks (e.g., order, family, and genus), to give expression to major monophyletic groups by naming inclusive taxa at intermediate levels. However, this usually means abandoning any equation of classificatory rank with clade level and any attempt to give all groups in the cladogram formal recognition. Thus, in a labeled cladogram of the main lineages of the order Lepidoptera (Figure 6), not all putative monophyletic groups are

named and all terminals (despite being almost completely noncoordinate) are classified at the same superfamily rank, except one of the cladistically most inferior groups, the crown group Ditrysia, which retains its higher, subordinal status accorded in earlier, precladistic classifications!

One partial solution to these difficulties is the sequencing convention, first proposed by Nelson. This attempts to combine the practicalities of a limited Linnean hierarchy with a listing that enables the entire (cladistic) hierarchy to be recovered. A sequence of taxa named at the same rank indicates that the first is sister to all following at that rank, the next is sister to the remainder, and so on. Taxa of uncertain position can be annotated as *incertae sedis* and those comprising unresolved polytomies as *sedis mutabilis*. In presenting these sequences, comprehension is greatly facilitated by indentation. Thus, the cladogram for the major groups of Lepidoptera in Figure 6 can be converted into a written classification (Table 5).

In conclusion, the idea that classification can simply be equated with systematization is a vestige of preevolutionary taxonomy and should be abandoned (Minelli, 1993, p. 14). In practice, reflecting a Simpsonian view, classifications are made consistent, as far as possible, with current systematization. Named para and polyphyletic assemblages are increasingly rejected whenever, *pace* Hörandl and Stuessy (2010), strong evidence of nonmonophyly becomes apparent. Such groups can be very misleading for comparative biology, biogeography, ecology, and extinction studies (although dicots, fish, reptiles, and invertebrates seem impossible to eliminate). Thus, dinosaurs are only extinct if we insist that birds are not part of the group – in other words, their extinction is a matter of semantics rather than biology if, by excluding the birds, we continue to treat a paraphyletic Dinosauria as if it were a natural entity.

Table 5 Sequenced, tabular classification of the Lepidoptera, reflecting Scoble's cladogram (Figure 4)

Order Lepidoptera
Suborder Zeugloptera
Suborder Aglossata
Suborder Heterobathmiina
Suborder Dacnonypha
Suborder Lophocoronina incertae sedis
Suborder Neopseustina
Suborder Exoporia
Infraorder Mnesarchaeoidea
Infraorder Hepialoidea
Suborder Heteroneura
Infraorder Incurvarioidea sedis mutabilis
Infraorder Nepticuloidea sedis mutabilis
Infraorder Palaephatoidea sedis mutabilis
Infraorder Tischerioidea sedis mutabilis
Infraorder Ditrysia sedis mutabilis

Restraint is also necessary to avoid unstable changes to the formal classification arising from partial or inconclusive evidence (careful use of consensus trees may be helpful here) and overelaborate nomenclature for the numerous hierarchical levels. With the real prospect of international consensus systems covering all major groups of organisms being developed on the Internet, a balance between stability and universally accessible periodic revision to reflect fundamental advances can be anticipated. Such IT-based bioinformatic systems should also solve most problems of information retrieval, including the ever-present difficulties of alternative classifications, synonymy, and misidentifications (the last being the most pernicious of all taxonomic problems affecting information retrieval).

Current Practice: Variations on a Cladistic Theme

Phenetics was afflicted by a proliferation of clustering algorithms, each tending to yield different results for which no logical criterion of choice was available. The vaunted objectivity of the approach dissolved, leaving the field of systematization open to the apparently more consistent and decisive methods of phylogenetic systematics. However, matters are rarely this simple.

In the 1970s, a partial schism opened between those phylogeneticists who followed directly in Hennig's footsteps, approaching character transformation from an evolutionary perspective, and the so-called transformed cladists (Patterson, 1982), who held that particular theories of evolution were unnecessary for cladistics, adopting instead a taxic approach to cladistic analysis (Kitching *et al.*, 1998). The transformed cladists embraced computer algorithms, character matrixes, and global parsimony, leaving polarization of characters to the algorithms and outgroup choice. For Hennig, the nodes in a cladogram were hypothetical ancestors; for the transformed cladists, the nodes indicate the hierarchical pattern of homologous characters. These differences have emerged in debate over congruence versus total evidence methods, now treated formally as partitioned versus simultaneous data analysis.

Because many cladists claim to have demonstrated the superiority of simultaneous analysis for making cladograms, this debate links in turn to a seemingly fundamental disagreement over whether or not to use Fisher's maximum likelihood statistics in phylogeny reconstruction, as first proposed by Edwards and Cavalli-Sforza and later implemented by Joseph Felsenstein as a general method (Huelsenbeck and Crandall, 1997). For a recent account and critique, see Schuh and Brower (2009, pp. 135–170).

However, the real source of these disagreements seems to be one of different scientific agendas: those in favor of model-based likelihood methods and partitioned data sets are mainly seeking insights into evolutionary processes, most notably those affecting molecular evolution within different lineages or under different constraints. Those rejecting likelihood models in favor of global parsimony and simultaneous analysis of heterogeneous data sets are primarily concerned with tests of homology and the construction of cladograms (but see Wiens, 1999). Both approaches have different strengths and weaknesses, and both make simplifying assumptions in pursuing these different goals (Kitching *et al.*, 1998, p. 165). Because most work affecting taxonomy requires the use of morphological data, or a combination of morphological and molecular data, for which plausible process models cannot readily be elaborated for simultaneous analysis using likelihood, the significance of likelihood methods for taxonomy per se (rather than understanding phylogenetic processes; Huelsenbeck and Crandall, 1997) remains to be demonstrated and is clearly rejected by some (e.g., Schuh and Brower, 2009).

However, with respect to the reconstruction of phylogeny there are several other methods, global parsimony and maximum likelihood being only the main contenders. These alternatives include James Lake's rate-invariant method for molecular data and pairwise distances (e.g., DNA–DNA hybridization). Even within the parsimony techniques generally adopted for cladogram construction, at least one fundamentally different challenge to global parsimony has emerged: three-item statement analysis, first proposed by Nelson and Platnick. Three-item analysis discards any presupposition that characters undergo evolutionary transformation and, by decomposing a taxon $\times$ attributes matrix into an analysis of all possible three-taxon statements supportable by the data, focuses entirely on evidence for sister group relationships rather than character transformations. Although not widely acclaimed or used, this method is operational and often yields more or less different results from those of conventional parsimony methods, thus raising some fundamental issues. For brief but informative discussions about this debate, see Kitching *et al.* (1998, Chapter 9) and Schuh and Brower (2009, pp. 133–135).

Conclusions

Taxonomy involves the search for a general pattern of order among living and extinct organisms, from which a general reference system (or classification) is derived. As such, taxonomy is the primary discipline of biodiversity. Fundamental philosophical disagreements about the nature of human

knowledge and reality have given rise to several basic methods. All recent approaches agree that systematics is empirical and should be based largely (evolutionary systematics and maximum likelihood molecular systematics) or entirely (phenetics and cladistics) on the comparison of data in the form of characters observed and abstracted from specimens. The methods differ somewhat with respect to the type of data preferred, and fundamentally with regard to methods of analysis used to reveal pattern, and how the system, once obtained, is translated into a written classification.

Cladistics has become the dominant method of systematization (where a preferred method is made explicit). The research program of cladistics is based on the view that the ideal general system should reflect the phylogenetic nexus. However, the true nexus cannot be known. If the precise course of evolution, taking account of all the relevant details of every lineage, is real but unknowable, then the natural system cannot be discovered but only approximated by an indirect process of estimation. Because cladistic classification can only admit monophyletic groups (based on the selection of a particular cladogram), all admissible groups are necessarily defined because they must have at least one unique (presumptively) homologous character (or a unique loss within a more inclusive group that is specified by some other homologous feature). If so, as suggested by both Rieppel (1988, p. 25) and Panchen (1992), the cladistic method is essentialist because the search for the sister group depends on the discovery of locally unique and thus defining shared characteristics for each and every group. Thus, Schuh and Brower (2009, p. 258) define apomorphy as a group-defining feature. Moreover, it has long been understood that although evolution is not bound by parsimony, scientific method admits nothing better than parsimony as the criterion of choice among competing hypotheses. Insofar as the divergent model of evolutionary history that justifies searching for a hierarchical pattern is flawed (Doolittle, 1999), the methods of cladistics may need further modification, notably to deal more adequately with hybrid origins and lateral gene transfer.

In conclusion, we may have to accept the seeming paradox that although the principle to which cladistics aspires is natural (i.e., the groups we seek to recognize exist regardless of human perception, and are thus to be discovered rather than defined; Rieppel, 1988, p. 163), its empirical methods appear in some sense to be inescapably essentialist (Panchen, 1992, p. 344). The basic method of taxonomy may be equivalent to the construction of a universal, never to be experienced directly but derived from the sensory experience of particulars (samples of individuals and characters) by means of an unending iterative sequence of analysis, hypothesis formation, testing, and reanalysis. This is a manifestation of the two ways of seeing explored by Rieppel (1988): the world of being owes its form to the processes of becoming, but those evolutionary processes can only be inferred indirectly from the patterns we observe in nature.

Finally, it is notable that approaches to the measurement of biodiversity that seek to maximize the number of expressible genes held in networks of germplasm banks or functional ecosystems depend on models incorporating information about branching sequences (cladistic relationships) and

branch lengths (anagenesis). In practice, the taxonomic hierarchy and the raw data matrix (before removal of homoplasy and autapomorphies) from which it has been derived will often be the best or the only available data for use in such models. For a review of this field, see Crozier (1997); see also Humphries (2006).

Glossary

Circumscription In the context of a name, the collection of things designated by that name.

Controlled vocabulary A set of terms, typically with an assigned meaning, used in datasets or for data exchange, to promote ease of data comparison.

Data-centric Particularly concerned with data.

Electronic resource Data or information in electronic form, especially accessible on the Internet. Also applied to Internet services, q.v.

EXIF Acronym for Exchangeable Image File Format. The full name is rarely used. It describes data often captured by digital cameras in addition to the image.

Geospatial Concerned with locations on the Earth.

GO Acronym for the Gene Ontology. This is a formal ontology used as a controlled vocabulary for gene annotation.

IANA Acronym for the Internet Assigned Numbers Authority. It is responsible for administering the syntax and use of named and numbered objects on the internet, such as the addresses that identify particular computers connected to the Internet.

IETF Acronym for the Internet Engineering Task Force, a body that promulgates standards for technical aspects of the Internet.

Informaticist One who practices informatics.

Informatics The practice of designing, implementing, deploying, and managing computerized information systems.

Internet service A remote software program on the Internet accessed by a user or by another program and which provides for some action to take place, or some information to be provided.

JPEG Acronym for Joint Photographic Experts Group. It describes a particular file format for digital images. The full name is rarely used.

Ontology A controlled vocabulary, especially machine readable, that provides for standard terminology, including relationships between the terms, for use in data description.

Optical character recognition The process by which an electronically scanned image of text is separated into individual characters and made available for electronic text processing such as by word processors. Often written only in its acronym, OCR.

Provenance A record, often electronic, of the origin of, and changes to data. Data provenance may include a history of the changes to the data, an authority for the data and its changes, and a way to recover the original.

Time stamp An electronic attribute of a data record or dataset that indicates when it was created or the last time it was changed.

History

Data is older than writing itself and arguably arose as early as the eighth millennium BC in the form of clay tokens that probably signified quantities of agricultural goods. Possibly as early as the sixth, but unambiguously by the third millennium BC, curation of that data had become more refined by sealing it inside clay envelopes with descriptions of the contents stamped on the outside. We can identify the earliest form of metadata in those stampings – the description of data or as it is now often characterized, data about data. The ubiquity of computerized acquisition, storage, and exchange of data creates a critical need for high-quality metadata, which is itself computerized. While many scientists recognize the need to be able to exchange electronic data in standardized formats, only recently is the awareness rising about the need for standards for the representation of metadata.

Many data-centric communities have metadata standards on which metadata standards for biodiversity information have been modeled. Historically, standardized electronic metadata is unambiguously recognized in the electronic cataloging of library collections promulgated in the Dublin Core Metadata Initiative (popularly known as the Dublin Core), organized originally by the Online Consortium for Library

Cataloging (OCLC). Dublin Core is a standard for describing library collection items (whether electronic or not). Natural history museums, herbaria, and botanical gardens have collections whose curation shares much structure with library collection management. Thus it is not surprising that the electronic description of specimens represents early standardization efforts by taxonomists, who, in at least one currently important case, emulated the OCLC efforts with a now widely used standard called the Darwin Core. This standard and a related, more comprehensive specimen description standard with the acronym ABCD (Access to Biological Collection Data) may be considered as modeling specimens as data, and therefore these standards merit the title metadata. Life scientists might argue this point, but computer scientists rarely distinguish data from metadata other than that metadata is data about some other data. Other early metadata standards of importance to biodiversity arose from governmental efforts to provide for the interchange of geospatial data as this became more easily accessible in electronic form throughout the last decade of the twentieth century. Recently the International Standards Organization (ISO) has established international standards for representing geospatial metadata – including the so-called country profiles, which recognize special governmental geospatial metadata needs of member countries.

Because so much geospatial data is provided by governments, scientists can expect that systems worldwide will begin to be compliant with the ISO standards.

Kinds of Metadata

Although there is no widespread agreement on any classification, metadata can be roughly divided into several kinds: acquisition, format, curatorial, normalization, and descriptive metadata. Thus, the Ecological Metadata Language (EML) recognizes information about where and when a certain set of data was gathered (acquisition metadata), who is responsible for its care (curatorial metadata), what are the units of measurement and permitted values for each field (normalization), whether the data is numeric or text (format), and what observations or measurements the various data represent (descriptive). Scientists have long recognized the need for standards in the expression of this sort of information, but all too often do not provide standardized metadata for their computerized data. For example, early in scientific education one is taught about the International System of Units (SI, from the French *Système international d'unités*) and a set of standard prefixes for scaling the fundamental units. This is a prime example of a standard for the expression of metadata, and without appeal to it or something equivalent, a table of measurements comprising only numbers is useless. Yet in computerized data, such tables are sometimes all that are recorded. Another kind of metadata, which allows the user to trace the history of changes to a database, is sometimes called "provenance" metadata. Although studied by computer scientists, its importance has received little attention among biodiversity informaticists, most of whose metadata standards presently express change in history only weakly.

Purposes of Metadata

Suitability of Data for Scientific Purpose

In the absence of adequate metadata, it may be quite difficult to decide whether a particular dataset is suitable for a particular scientific inquiry, or to know how it might be compared with data from another source. For example, the US Geological Survey offers vegetation coverage data for the Arctic National Wildlife Refuge, with a carefully constructed metadata file containing, among other things, the descriptive names of 23 classes of land cover that are represented in the satellite-derived data, along with a reference to a technical report describing how that data was deduced from the raw remote-sensing data. With this metadata, a climate change investigator might better support a study investigating change in vegetation correlated to climate change data than if only the raw remote-sensing data was considered. In such cases, the metadata plays a role much like the familiar methods section of traditional scientific publications; it allows those considering the data analysis to decide whether the data was properly used.

Data Discovery

On the Internet it is often quite difficult to locate and exploit electronic resources, especially those hidden behind databases (sometimes called the deep web). This problem is even more severe when the search is not controlled by a human but rather by a semiautonomous software application, for example, an ecological modeling program using data distributed around the Internet. Although a human usually controls data access, when the data is in electronic form it is always accessed in the first instance by software, such as a web browser or a database application package. For control by software, two important pieces of metadata are always needed: where to locate the data and how to access it.

Data access software can be made substantially more powerful if it can automatically discover the location, access methods, and standard metadata of new data sources that have become available subsequent to the deployment of the software. Several solutions to this are common. Among them are data portals, and dereferenceable globally unique identifiers. The latter have become particularly useful for "Linked Open Data," a Semantic Web technology described below.

Data Portals

A data portal is a single Internet site at which the data discovery and delivery tasks are delegated to software. Superficially, the data portal eliminates the data discovery problem. In reality, the portal software has merely taken the discovery burden off the user (whether human or software) onto itself, often by some form of metadata registry access. Expertly run, this can be very useful. For example, The Global Biodiversity Information Facility (GBIF) operates a portal that aggregates several hundred million records that document the occurrence of a species, based either on a specimen in a natural history collection, or on a field observation. These records come from several hundred different data providers that software or humans can query for more detailed information.

Globally Unique Identifiers

Substantial attention is now being given to a special kind of metadata to assist in the discovery of electronic resources. This is the Globally Unique Identifier (GUID). One GUID scheme widely used by publishers is the Digital Object Identifier (DOI). Like all GUID schemes, DOIs must be issued according to some process that guarantees no two electronic objects are ever assigned the same DOI, and a nonprofit organization is established to do that. The Biodiversity Information Standards (TDWG) organization (named from its historical name, the Taxonomic Databases Working Group) and GBIF have explored a different GUID scheme for their data-exchange standards. This is the Life Sciences Identifier (LSID), which is also in some use for genomics data. GUID is a rather generic term, with no standards for its use. The Internet Engineering Task Force (IETF) has promulgated a standard for a kind of GUID called a Uniform Resource Identifier (URI), along with a procedure for registering the syntax of a URI with the Internet Assigned Numbers Authority (IANA). Both DOI and LSID are registered URI schemes. An increasingly important registered URI scheme long in use on the Internet is that based on the familiar syntax for the address of web sites, the

so-called “http URI scheme.” All of the examples are “dereferencable URIs,” meaning that from the URI alone, software can reliably discover and retrieve datasets or even individual records from, or at least further information about, the online resource identified by the URI.

Data Provenance and Quality Control

Because taxonomic synonymy may, for example, make a binomial species name ambiguous, data can for some purposes have its utility impaired unless some authority for the name is given. When the data involve the identification of a taxon, an ecosystem type, or identification appealing to some other classification of the objects represented by the data, the metadata often contains the authority for the classification as well as for the particular identification. Particularly important, but often overlooked, it can be critical in such a case to have metadata indicating the date at which the classification was made. This is because the names of things – for example, taxa and places – can have their circumscription change over time by such activity as taxonomic revision or geopolitical events. In the absence of such time stamp metadata, it may be impossible to tell exactly what is described by a name found in a dataset. Time stamps are an example of what is called record-level metadata, because they often must be applied to each data record rather than to the dataset as a whole unless changes to individual data entries are prohibited. Other important provenance metadata might include information about the authority for a taxonomic determination and the original source of the record in the case that a third party, for example, a portal, is providing the data.

Data provenance can help provide evidence for the quality of individual data records by providing a trail to the original source of the data, and to changes that may have been made. However, the use of provenance is not the only way to automatically find some kinds of data errors, such as those arising from human data entry or from programming errors. Systems that apply rules about the semantic nature of the data are also often employed to find logical inconsistencies in the data. For example, if a dataset of species occurrence contains an attribute describing whether the species is terrestrial or marine, then software with access to the boundaries of marine bodies can detect such errors as the exchange of latitude and longitude values in a dataset that might result in data showing the occurrence of a terrestrial organism in an ocean.

Annotation

In genome science it is commonplace to annotate data with additional information about a gene’s function, its relation to other genes, or other attributes beyond just its nucleotide sequence. Data searches based on such annotation can help find patterns in genomic data that represent a higher level of knowledge than the sequence alone. Recent informatics research efforts have begun to explore biodiversity data record annotation using approaches and technologies similar to those of genomics, with the expectation of similar benefits.

Beyond Spreadsheet Headings: Structured Metadata

Obstructions to Machine Integration of Heterogeneous Biodiversity Data

Even when describing the same scientific concerns, for example, the same group of taxa and the same ecological questions, scientists often have experiment, modeling, or collection protocols that suit their precise investigation. Variation in these gives rise to heterogeneous data, which can be very difficult to share and combine. In the past, this problem was often addressed with tedious cooperation between database administrators in ways that might require special-purpose manipulation that often did not survive evolution of the database, such as adding new data tables. With dramatic decreases in the costs of gathering data and making it available immediately on the Internet, these *ad hoc* data integration methods are no longer satisfactory and new support for data integration is emerging.

There are several requirements for addressing this problem technologically. The most important is controlled vocabularies within disciplines to provide common terminology for representations of data and metadata. The second is a common way to express that terminology – a sort of lingua franca – suitable for computer processing. A widely accepted solution to the latter problem has arisen to meet the needs of non-scientific users of the Internet – principally those engaged in electronic commerce – that has been embraced by many scientific communities. It is a computer language called the eXtensible Markup Language (XML). Correspondingly, many scientific groups have been organized to produce common terminologies expressed in XML.

XML and Data on the Internet: Metadata for Metadata

XML is now a ubiquitous way of expressing data in an extremely portable fashion, making it particularly easy to share data on the Internet. XML data is often characterized as self-describing, which in one sense can be considered as carrying its metadata with it. It does so by surrounding data with tags carrying descriptive metadata. XML is expressed in human-readable form, but in reality most XML is too complex for humans to read it without special software. However, because so much Internet technology has been devoted to human-to-human communication, human-readable forms are more reliably exchanged than many specially encoded forms of computerized data. This fragment of a type specimen record for the oak *Quercus obtusata* illustrates the point. It is expressed in the Darwin Core XML form. The tags are the expressions in brackets.

Source: The Darwin Core data record for *Quercus obtusata* was obtained from the Type database of the Danish Biodiversity Information Facility.

If one takes the liberty of considering the specimen itself as data, then the text and numbers between the tags are a kind of metadata for that data, and the tags are metadata for that metadata. In practice, the specimen record would normally reside in a standard database, in which case the XML tags can then more clearly be seen as metadata, for example, the names of attributes in a relational database. The Darwin Core metadata is not arbitrarily organized. Instead it corresponds to a published set of structural rules playing much the same role as the taxonomic nomenclatural codes play for taxonomic names. In this case, these rules are themselves expressed in XML, in a form called XML-Schema, and accepted as an international standard by TDWG. The Darwin Core is employed in the GBIF portal, as is a related but more complex XML-Schema, the ABCD, both mentioned earlier. Tightly controlled by the XML-Schema rules, these standards make it possible to combine and compare data across species, data providers, locations, or any of the other kinds of data they represent.

Ecological Metadata Language

EML is the metadata standard most directly addressing ecological data. It has many components of each type of metadata mentioned earlier in this article (*see* Kinds of Metadata). Of special note, the organization promulgating EML – the Knowledge Network for Biocomplexity – also provides

software that supports metadata repositories and catalogs (and even collaborative data repositories) in ways that make it easy for scientists to maintain their data in their own database systems or spreadsheets. Although EML is represented in XML, these software products make it unnecessary for scientists to know about the inner workings of either XML or EML.

Below is a fragment of a metadata item represented with EML tags. It expresses where, how, with what kind of numeric measurement, and with what units and precision a certain temperature is regularly recorded.

Darwin Core and BioCase Access to Biological Collections Data Metadata Standards for Specimens

The Darwin Core and the ABCD metadata standards both aim to describe natural history specimens and both have been extended to descriptions of field observations of organisms. These two standards exhibit a common tension in the design of metadata standards: whether to be economical or to be inclusive. For example, the ABCD standard admits seven different kinds of specimens or observations (microbial, mycological, herbarium, botanical garden, plant genetic resources, zoological, and paleontological), each with a different structure. By contrast, Darwin Core makes no such distinctions. While it is easier to conform to a simpler standard – perhaps leading to wider acceptance – it is correspondingly more difficult to use metadata thus expressed to locate data with specific properties. For example, using Darwin Core could require special knowledge about the nature of institutions holding the records to ascertain whether a particular plant specimen is alive or not, whereas in ABCD such specimens would typically be tagged as being in a botanical garden.

Metadata Standards for Geospatial Data

Locations and geographic extent of biota, populations, and ecosystems are so central to biodiversity information that access to geospatial data plays a key role in many biodiversity

information systems. All the standards discussed above have some way to describe geospatial data, but often their commonality lies only in the simplest expressions, such as that for the latitude and longitude of a point and an error radius. The Open Geospatial Consortium (OGC) has developed not only standards for geospatial data and metadata, but also guidelines for how to exploit those standards in the development of other standards. A somewhat simpler standard was proposed in 2010 by the IETF and is finding wide use for web-accessible data, particularly where only point data is available.

Emerging Metadata Technologies and New Applications of Metadata

The Semantic Web: Machine Reasoning about Comparing Databases

An increasingly important role of biodiversity metadata arises from the ease with which data is now shared on the World Wide Web coupled with the difficulty of locating and evaluating the utility of such data for any particular scientific inquiry.

In an attempt to mitigate issues surrounding the aggregation of datasets on the Internet with widely differing descriptions of their data, the World Wide Web Consortium (W3C) has promulgated a metadata language with the acronym RDF (Resource Description Framework). This specialized language (most often expressed in XML) builds on a history of computer science research dealing with diverse descriptions of the same thing. A further specialization of RDF (together with some other W3C XML standards) forms the Web Ontology Language (OWL). Computer ontologies support the expression – in this case in XML – of the objects of a discipline, their properties and the relations between those properties, between objects, and between classes of objects. Other ontology expression languages important for biological sciences include those of the Unified Medical Language System (UMLS) and of the Open Biomedical Ontology (OBO) format. The well-known Gene Ontology (GO) has expressions in OBO and OWL.

An important focus of ontology languages is their support for machine reasoning. By use of relations expressed in OWL or OBO, and to a lesser extent in RDF in general, it is possible for computer software to draw conclusions about the relations between data records. This holds the promise of successful data discovery and integration when different data sources have different controlled vocabulary in their metadata or when the seeker has a different way of conceptualizing the data than might be represented in available databases. In some simple cases, machine reasoning can even discover inconsistencies within or between datasets that might otherwise lie hidden. Somewhat more advanced is the capability for such software to test whether a given dataset is logically consistent with one or another model expressed as an ontology. This promise is in its infancy though, in part because it is quite easy when using these technologies to build ontologies that are computationally intractable. Ongoing biodiversity informatics efforts in ontology development and application hold promise in describing such diverse studies as phenotypic

variation, ecological relations, and the application of environmental sensor data to ecological investigations.

RDF has found use in a simple set of Internet best practices collectively denoted “Linked Open Data (LOD).” These practices make it easy for online data holders to link their datasets to other related ones. The resulting “web of data” comprising all these links make it easy to provide services that an ordinary web browser can navigate. More sophisticated browser applications allow the user to choose the data relations that they wish to guide their browsing. Such facilities reduce the burden and increase the utility of scientific data sharing.

Extracting Knowledge from Scientific Literature

XML is derived from a computer tagging language called the Standard Generalized Markup Language (SGML), which dates to research in the 1960s at the IBM Corporation. SGML was designed primarily to tag (or “mark up”) electronic documents. In this context, the tags are often called document markup. Such tags help identify the structure and meaning of the document, and – using XML – are now being rapidly applied to digitized forms of existing scientific and other scholarly and cultural literature. In this process, images of the pages are made by the use of scanners, and optical character recognition turns these images into plain text. The markup is applied by knowledgeable humans, or increasingly often, by software programs with human intervention only for proof-reading and correction. Nevertheless, without full automation the markup task is immense. By the end of 2010, the Biodiversity Heritage Library had scanned nearly 33 million pages of published literature, but the best present markup correction tools require 2–3 min per page of effort by biologists. As with data, such markup forms a kind of descriptive metadata for the form and content of the documents and enhances the ability of the software to discover and extract information from literature not previously available in digital form. Recent advances in electronic publication make it easier to do this as part of the production of born-digital publications, and the resulting markup can provide such things as intelligent searches of newly published biosystematics literature.

Amplifying the Utility of Digital Media

An increasingly important form of data consists of digital media such as images, sounds, and movies. Many of the digital formats for the exchange of these media support limited metadata standards, which, moreover, can be embedded in the digital representations along with the data, making the metadata curation more robust. For example, most support an early metadata standard with the acronym EXIF that consists mainly of acquisition metadata that is often automatically added to the media by the acquisition system itself (including, e.g., acquisition date, image size, camera, and lens details). For web-accessible data, the ability of the data to carry its own metadata provides some advantages: once the location and electronic format of the desired data is known, the precise description of the data can, in principle, be extracted from the data itself, much as happens with XML data representations.

EXIF metadata can be manipulated and extracted by many image-processing programs.

A 10-year-old standard for image data files, JPEG2000, is an improved format over the classical Joint Photographic Experts Group (JPEG) format widely used by digital cameras. JPEG2000 can represent still pictures, video, and audio. Arbitrary XML data can be embedded in a JPEG2000 file, which can carry multiple images or other media within the file. In particular, JPEG2000 files can carry extensive metadata, conveying much more information than is specified by EXIF, which has very little provision for descriptive metadata. For example, remote-sensing vegetation images can carry with them the vegetation types corresponding to each color in the image and suitable software could automatically construct a color key when displaying the image, or images of plant specimens could include Darwin Core specimen records with them.

A recently adopted TDWG standard, the Audubon Core Multimedia Resource Metadata Schema makes it easy for providers of biodiversity images, video, and sound to better to describe the content of their media resource. In many cases, this metadata alone can be combined with other species occurrence data for studies such as niche modeling, seasonal variation, climate change, migration, and other investigations that depend on geocoded occurrence data.

Scientific Workflow Systems

Workflow systems are software systems that conveniently allow data analysis to be done automatically with analysis provided by packages chosen and organized by the user. Typically, these provide for inclusion of popular statistical and

modeling packages that are already familiar to scientists. They often make use of the metadata for their inputs to ensure that the data are meaningfully combined by the packages, and some more advanced workflow systems are capable of locating and exploiting data on the internet in combination with the user's own data.

Biogeographical Models

Thiago F Rangel and JAF Diniz-Filho, Federal University of Goiás, Goiás, Brazil

Glossary

Empirically derived correlative model A model that generalizes the observed relationship between patterns of species richness and one or more predictors by means of a linear or curvilinear equation. Inference drawn from these models is often limited to qualitative evaluation of the explanatory power of predictors.

Species distribution model A model that attempts to describe and understand the geographic distribution of species, usually through interpolation and/or extrapolation of empirically derived correlations between the environmental factors and the presence/absence of the species.

Species richness The number of taxa found at a given location, at a given time. Measures of species richness are strongly affected by spatial and temporal scale.

Stochastic simulation model A spatial and/or temporal dynamic model that characterizes discrete agents (usually species), and the mechanisms hypothesized to affect properties of these agents. Unknown mechanisms or known mechanisms not included in the model are represented by stochastic processes.

Theoretically derived correlative model A model that is derived from fundamental and lower-level scientific principles in the form of a mathematical equation, and is evaluated through a correlation between its prediction and observed data.

Introduction

Biogeography is concerned with the causes of geographical distribution of species and biological entities at high hierarchical levels, and with their dynamics through evolutionary time (Lomolino *et al.*, 2009). Biogeographical dynamics of multiple species in space and time generate emergent patterns, especially of species richness and turnover, across a wide spectrum of organizational scales. These patterns are also influenced by a complex set of extrinsic (i.e., ecological or environmental, and evolutionary or historical) and intrinsic (i.e., life history, physiological, behavioral, and morphological) factors and their interaction.

Because of the broad geographical and temporal scales usually involved in determining patterns of biodiversity, it is difficult to test hypotheses about each particular ecological and evolutionary mechanism that is thought to drive the biogeographical patterns. The principal existing approach to this problem relies on statistical analysis of patterns in relation to environmental characteristics. This approach provided the first important evidence about these hypotheses and has since been widely employed in biogeographical studies. However, as explained below, correlative modeling is not a strong tool for understanding or discriminating the underlying mechanisms behind biodiversity patterns. Controlled experiments offer a more powerful way to understand complex phenomena, but unfortunately the spatial and temporal scales on which hands-on experiments are feasible (and the relatively constrained circumstances under which they are ethical) place such experiments out of reach for many compelling and longstanding questions. Scientists in other fields whose objects of study cannot be manipulated, such as astrophysicists interested in the internal structure of stars, have taken advantage of high-capacity computers to carry out virtual experiments on simulated systems designed from first principles. This strategy has only recently begun to be applied to understand

biogeographical and macroecological patterns and processes (Gotelli *et al.*, 2009).

Models can be built to explain many different biogeographical patterns, but here we focus on models for species richness patterns, because they illustrate how biogeographical models have progressed during the recent decades and have been a focal point in the development of the field. In as early as the eighteenth and nineteenth centuries, naturalists and biogeographers described and documented what today we call geographical (latitudinal) gradients in taxon diversity (species richness), in which diversity decreases from the tropics towards temperate and polar regions for most taxa (e.g., Willig *et al.*, 2003). The number of species of organisms varies greatly over the continents of the Earth, from species-poor habitats at high latitudes, high elevations, and in arid ecosystems to species-rich habitats in the wet tropics (Hawkins *et al.*, 2003b; Willig *et al.*, 2003). Surprisingly, even after 200 years of research in biogeography and ecology and some important advances mainly in the last 20 years, there is still no clear understanding or consensus on how these patterns arise and are maintained (Hawkins, 2001). What no one doubts is that many interacting causes are at work, and this in turn demands the development of increasingly complex approaches to deal with the problem (Figure 1).

The recent conceptual development in the new field of macroecology (Brown, 1995; Gaston and Blackburn, 2000) triggered a demand for more theoretically oriented analyses of biogeographical patterns, in which ecological and evolutionary mechanisms underlying the patterns are simultaneously incorporated into the model, rather than simply documenting or describing the patterns themselves. Biogeographical models have evolved from the simple correlative approach, with increasing degrees of complexity in their predictions, to analytical and theoretically oriented approaches. Finally, during the recent years, biogeographers have begun to develop complex, spatially and temporally explicit computer simulations,

Figure 1 Maps of species richness of bird, mammal, and amphibian species richness in the Western Hemisphere.

Figure 2 Relationship between species richness of birds, mammals, and amphibians and actual evapotranspiration (AET) in the Western Hemisphere.

designed to account for multiple interactive causes and the stochastic nature of biological entities.

Correlative Models

Initial hypotheses explaining geographical patterns in species richness were deduced solely by observing and describing nature, and were based on nothing more rigorous than an intuitive and loose correspondence between a factor (usually climatic) and biological patterns. Influential early examples include analyses by A.G. Fischer (Fischer, 1960), by G.G. Simpson for North American mammals (Simpson, 1964), and a conceptual review by E.R. Pianka (Pianka, 1966; see Hawkins, 2001 regarding contribution by even earlier researchers). Many other hypotheses were developed, but most of them were restricted to particular groups of organisms, and were empirically derived or untestable (Rhode, 1992). Whittaker *et al.* (2001), Rahbek and Graves (2001), and Willig *et al.* (2003) reduced the large number of initially available hypotheses to a much smaller number of testable and general set of hypotheses, including energy availability, evolutionary time, and habitat heterogeneity, as well as area and geometric constraints, providing a better framework for testing each hypothesis. Of course, testing each of these groups of hypotheses requires establishing environmental or evolutionary surrogates for each of them. For instance, temperature is usually used as a surrogate of energy hypothesis, and actual

evapotranspiration (AET) is used when one wants to test the coupled effects of water and energy availability (e.g., Rodriguez *et al.*, 2005). This correspondence is not of course undisputable and may be scale-dependent. A good example is using elevational range (within a species geographical range or habitat) as proxy of habitat heterogeneity, when, in fact, elevation can also be considered a surrogate of isolation and speciation rates.

Until recently, the most common framework used in such investigations still relied primarily on statistical measurements of the concordance between the broad scale spatial patterns in species richness and multiple environmental factors (e.g., Currie *et al.*, 2004). The generally strong relationship between species richness and some of these environmental factors, especially particular balances between water–energy measured by AET, has led many researchers to conclude that environment (e.g., climate) is the main driver of species richness, based on a purely correlative view (Figure 2; Hawkins *et al.*, 2003a,b). However, although the correlative approach provides the most straightforward description of the relationship between climate and patterns of species richness, it falls short at disentangling causal links. Nonetheless, many researchers have derived more complex predictions and employed, elegantly, correlative tools to quantify and test biogeographical hypotheses. Improving these tests, however, may require the development of auxiliary hypotheses based on different variables, or the deconstruction of observed patterns. For example, one may study how energy and productivity affect the patterns

of species abundances, as these two environmental factors are usually invoked as the mechanism driving richness gradients, assuming that higher number of individuals promote higher species richness (e.g., Currie *et al.*, 2004). Another example is the comparison of richness patterns between current and past modeled environments (Araújo *et al.*, 2008; Hortal *et al.*, 2011), or the deconstruction of richness patterns into basal and derived taxa to test for niche conservatism (Hawkins *et al.*, 2007a, b; Davies *et al.*, 2011). The deconstruction of biogeographical patterns by range size quantiles (at the simplest, small- vs. large-ranged species) has yielded both new understanding and some surprises (Lees *et al.*, 1999). Meta-analytical techniques can also be used to better understand in which situation (i.e., groups of organisms, spatial scales) gradients tend to appear or are being driven by a particular set of environmental factors (e.g., Field *et al.*, 2009).

Although climate surely has a strong effect on biodiversity patterns, as the geographic distribution of individual species is limited by the overall bioclimatic envelope within which the species is able to survive (Soberón, 2007), there are many pathways by which climate can be linked to diversity. For instance, from a population ecology perspective, it is not difficult to understand why increasing levels of water–energy allows higher carrying capacity in a given locality, but there are still large conceptual gaps to be filled before we understand how a larger population (number of individuals) promotes an increase in the number of species (biodiversity; Currie *et al.*, 2004). Filling these gaps requires the understanding of additional ecological and evolutionary mechanisms that act in concert, such as species interactions and their evolution, niche dynamics, dispersal mechanisms, and the balance between speciation and extinction as functions of mutation rates (Ricklefs, 2006).

An important class of correlative models has been widely used to model species distribution, roughly based on niche concepts (Soberón, 2007; Colwell and Rangel, 2009). These models, generally called Species Distribution Models (SDMs; or niche models; Peterson, 2006), are based on the overall reasoning of modeling the presence (and/or absence) of species as a function of environmental variation. Today there is a wide array of SDMs, ranging from a very simple bioclimatic envelope model (in which the species is assumed to be present everywhere within the environmental limits of its distribution) to complex artificial intelligence-machine learning models, such as neural networks and maximum entropy models. There are many discussions about how well these models determine species' distributions (Elith *et al.*, 2006; Elith and Graham, 2009), but it is more or less clear that they tend to represent potential distributions in the absence of other factors, such as dispersal limitation, historical constraints to distributions (barriers), and biotic interaction (Guisan and Thuiller, 2005). SDMs are currently quite widely applied, and have been primarily used in more applied biodiversity and conservation studies, i.e., to understand the effects on diversity patterns of climate change or invasive species.

Guisan and Rahbek (2011) recently developed an interesting framework, called Spatially Explicit Species Assemblage Models (SESAMs), in which richness maps obtained from what they called macroecological or top-down methods (i.e., empirically derived from observed range maps) are compared

with maps derived from bottom-up methods (obtained by summing SDM maps). The framework consists of evaluating if broad scale diversity patterns can be considered a consequence of ecological processes acting at the level of species' ranges, and evaluating how other processes (i.e., dispersal limitation, historical constraints, or biotic interaction) can explain deviations between top-down versus bottom-up mapped patterns. For example, if a region is expected to have a high richness based on SDMs but there is actually a smaller number of species, this may be due to isolation and systematic lack of dispersal towards this region (a geographical dispersal constraint), or perhaps there are assemblage rules that reduce the coexistence of species in the region (biotic interaction such as competition). However, if a region harbors more species than expected by SDMs, one could evaluate if that region is prone to speciation (or buffered against extinction) independently of baseline environmental drivers of species distributions. Although further applications and tests of the protocol are needed, we believe SESAM certainly opens a significant new research avenue in macroecology, especially on how broad scale patterns emerge from species distributions, and hopefully the strategy will allow better inferences about mechanisms and will provide a more comprehensive view of how diversity patterns evolve at different hierarchical levels.

Indeed, one of the important conceptual problems of the “purely” ecological (contemporary) drivers of biodiversity patterns is the time-lag response of biodiversity to climate, and how climatic changes throughout ecological and evolutionary time have driven current diversity patterns. In fact, the protocol proposed by Guisan and Rahbek (2011) can be potentially useful to evaluate if the responses of biodiversity to climate are structured in time. As pointed out by Ricklefs (2006), it is surprising that, despite these advances, the evolutionary components underlying widespread correlations between climate and species richness remain so poorly understood. With regard to short ecological time scales, recent developments in climatic modeling allow us to understand changes in climate during the last few thousand years, which in turn opens the possibility of understanding how climatic stability is related to species richness. The biogeography of species in the Northern Hemisphere after the last glacial maximum provides important clues on the temporal rate at which biotas reach “equilibrium” with climate (Hawkins and Porter, 2003; Araújo *et al.*, 2008; Hortal *et al.*, 2011). Moreover, it has been demonstrated that diversity tends to accumulate in more climatically stable (usually warmer) areas, by allowing more time for adaptation and specialization, whereas unstable regions (usually cooler) are typically occupied by good dispersers that have evolved and maintained adaptations to these cooler regions (Dynesius and Jansson, 2000).

At deeper time scales, there is a growing consensus that correlations between diversity and climate arise as a byproduct of the combined evolution of climate and niche conservatism, which is a version of the environmental stability–richness mechanism (i.e., Wiens and Donoghue, 2004; Wiens *et al.*, 2010). As temperatures in the currently temperate regions declined in the last 30 million years, species previously adapted to widespread tropical climates contracted their geographic ranges or became extinct, creating a gradient between tropical and temperate regions. As evolutionary novelties

arose, eventually adaptations to cooler environment allowed species to colonize and diversify in the temperate regions. Notice that this explanation explains the evolutionary history of clades adapted to Miocene tropical environments worldwide, but fails to explain the biogeography of clades that evolved in a time when the planet was cooler, which by the same logic would produce a richness gradient inverse to what we see at present. If this concept is correct, for any given clade there should be a correlation between the direction of the latitudinal gradient of species richness and the time and place of origin of the clade.

The scenarios described above can be tested if dated phylogenies (and reliable fossil records) are available for a clade, as they can be used to draw predictions about the distribution of species' ages across space or the degree of phylogenetic clustering of species in the tropics compared to temperate regions (Hawkins *et al.*, 2007a, b; Hof *et al.*, 2010; Davies *et al.*, 2011). Alternatively, it is also possible to try to determine, using similar phylogenetic information, if the tropical–temperate gradient is driven by distinct balances between speciation and extinction rates (Weir and Schluter, 2006). However, most phylogenetically explicit tests of niche conservatism have been done at species or clade level, treating environment as a cross-species trait (e.g., Wiens *et al.*, 2006; Diniz-Filho *et al.*, 2007; Hof *et al.*, 2010). Algar *et al.* (2009) proposed an explicit test for these patterns of niche conservatism by using combined metrics for phylogenetic diversity applied to distinct regions across an environmental gradient, and this may be a helpful starting point for exploring a more explicit link between niche conservatism and richness variation. It is very likely that alternative balances between the relative importance of processes more related to geographical patterns of diversification and extinction or niche conservatism are found for different groups of organisms in different parts of the world, but still better methods to quantify this balance need to be developed.

The correlative approach provides a straightforward framework to test hypotheses when they are derived from conceptual predictions, but there are pitfalls that require caution. Correlative models do not allow the dissection of multiple causal links when the surrogate factors (i.e., regression predictors) are collinear, or when multiple factors drive patterns at the same time but at different geographical scales. Thus, it is difficult to integrate local (biotic interactions) with regional (climatic) factors into correlative models (but see Gotteli *et al.*, 2009) or to disentangle the role of each factor in driving species richness on a broad spatial scale.

A fundamentally different class of models for broad scale latitudinal gradients has been developed during recent years. These models are based on the theoretical understanding of the effect of environmental variables on organismal metabolism and physiology, or on population dynamics (e.g., Allen *et al.*, 2002; Field *et al.*, 2005; O'Brien, 2006). These models are important from an epistemological view-point, as they make reasonably precise predictions about the relationship between broad scale patterns of species richness and temperature, and therefore provide hypotheses that are falsifiable from a Popperian perspective (but see Hawkins *et al.*, 2007b). However, as explained below, models of this class use the same statistical background, and therefore are still considered “correlative”.

Some of these pioneering models, such as Interim General Models (IGMs) applied to plant diversity, try to understand, based on overall knowledge of plant physiological and ecological responses, which variables (mainly in the sense of water balance and habitat heterogeneity) account for broad scale patterns of species richness. O'Brien (1993, 1998) developed a mechanistic model (the “biological relativity to water–energy dynamics” model) in which there is a linear relationship between richness and rainfall, and a parabolic relationship between richness and insolation. Field *et al.* (2005) developed and compared a series of IGMs by fitting empirical models under the same physiological–ecological reasoning at a local or regional spatial scale and then projected these models to a global scale, showing a good match with macroecological models developed for plants (Currie and Paquin, 1987).

One of the most widely discussed correlative models derived from “first biological principles” in the context of broad scale richness patterns is based on what has been called the Metabolic Theory of Ecology (see Brown *et al.*, 2004 for a summary, and Hawkins *et al.*, 2007a,b for a critique). Allen *et al.* (2002) proposed that richness (S) is a function of temperature:

$$\ln(S) = -(E/1000k)(1000/T) + C$$

where C is a constant, E is the activation energy (0.78 eV), k is Boltzmann's constant (8.62×10^{-5} eV K⁻¹), and T is temperature measured in Kelvin units. This model predicts that richness, on a logarithmic scale, decreases 9 species as 1000/ T increases (see Brown *et al.*, 2004 for a different parameterization). Allen *et al.* (2006) further expanded this model and tried to merge it conceptually with neutral evolutionary dynamics, using similar analytical predictions for the relationship between evolutionary rates and temperature. However, this more complex version of the model is difficult to test empirically due to lack of data. Hawkins *et al.* (2007a) tested the simple model of Allen *et al.* (2002) using several macroecological datasets and showed a poor fit in almost all cases, opening a wide-ranging discussion about the predictive and explanatory generality of such a model (Hawkins *et al.*, 2007b; Latimer, 2007; Gillooly and Allen, 2007). However, even if generality and explanatory power of the model is dismissed, there may still be important lessons to be learned before a full rejection of the metabolic theory as applied to latitudinal gradients. In fact, Cassemiro and Diniz-Filho (2010) showed that the model of Allen *et al.* (2006) is highly sensitive to model assumptions, and when they are met, and other factors driving gradients are ruled out, model fit may improve significantly. Obviously, this finding shows that the model may not be as general and powerful as originally proposed by Gillooly and Allen (2007), but clearly the model still provides important clues on how and why species respond to environment.

Lessons learned from correlative models suggest that it is reasonable to assume that patterns of biodiversity are driven by a wide array of factors, which interact across spatial scales, including speciation, adaptation, dispersal, species interactions, extinction, and habitat heterogeneity. The model of Allen *et al.* (2002) has many strong assumptions on how biogeographical patterns arise and are maintained, and to a

great extent these assumptions are the reason that the model is unable to predict empirical patterns. Typically, analytical models for massively complex natural systems have a limited utility and applicability, even for specific cases (Wiegand *et al.*, 2003). In addition, correlative models are typically unable to deal with the effects of interactions among multiple ecological mechanisms and to deal with contingencies or stochasticity throughout the evolution of species and niches. This leads us to our last class of models, those based on computer simulations.

Stochastic Simulation Models

Ecologists (Peck, 2004; Grimm *et al.*, 2005) have recently followed philosophers of science (Winsberg, 1999, 2001, 2003), physicists, climate modelers, and others in arguing that experimental methods need not be limited to concrete systems but can be legitimately applied to computer simulations of reality that have been carefully constructed to reflect known, underlying processes. Experiments on simulated systems, just like experiments on real ones, are constantly in dialog with theory and abstract models on the design side, and with statistics on the results side.

Based on the above epistemological reasoning, it is now possible to take advantage of high-performance computational capacity to investigate richness patterns by carrying out virtual experiments on simulated systems. This approach allows the designing and building a sequence of increasingly realistic, spatially and temporally explicit computer models of biogeographical patterns based on well-understood evolutionary and ecological processes, including species origination, adaptation of niches to environments, expansion and contraction of geographic ranges, and extinction. By design, these models are intended to be simple enough to be understood and controlled, but realistic enough to support meaningful simulated experiments and test hypothesized biological mechanisms that are thought to drive patterns of species richness. In the most realistic models, simulated species populate maps of real regions and continents and the resulting patterns of richness can be directly compared with corresponding patterns based on high quality biogeographical data, to discover which model variations come closest to matching nature.

The application of simulation approaches to macroecological analysis of richness patterns was triggered by the discussion of the null models appropriate for testing such patterns, within a more statistically oriented conceptual view. Colwell and Lees (2000) argued that the geographical ranges of species are geometrically constrained by hard boundaries within a region (i.e., a domain), forcing an increasing overlap of the geographical ranges towards the center and, consequently, a mid-domain peak of species richness. They originally suggested that this Mid-Domain Effect (MDE) could be treated as a null model for gradients in species richness with respect to environmental factors, as the model assumes that species' geographical ranges are randomly placed over the domain in the absence of (or despite the presence of) environmental gradients. Perhaps needless to say, the most used implementation of such models involves computer

simulations (e.g., Colwell and Hurtt, 1994), although some analytical versions of MDE model have also been developed (Bokma *et al.*, 2001; Connolly, 2005). Of course, defining the correct null expectation for the gradients of species richness in the absence of environmental factors, against which correlative and mechanistic models could be contrasted, is an important leap forward in the study of broad scale geographical patterns. Later, Colwell *et al.* (2004) suggested that geometric constraints imposed by hard boundaries was not only a null model strategy to study spatial patterns of species richness in the absence of any effect of environmental drivers, but could also be treated as an additional factor directly influencing spatial patterns in species richness, and therefore should be evaluated as a competing or contributory explanation for those patterns.

Jetz and Rahbek (2001) designed an ingenious strategy to generate expected species distributions in two-dimensional maps in the absence of the influence of environmental factors. The algorithm is analogous to placing a drop of dye onto a bounded and homogeneous surface. The dye naturally spreads towards all directions within the surface, but the spreading of the dye is limited by the boundaries of the surface. The so-called "spreading dye" model starts by listing species that are present in a given discrete domain, noting their respective range size (number of occupied grid cells for each species). Then, for each and every species, a "starting" position is chosen randomly and independently among all possible grid cells of the domain. The simulated distribution for a species is created by sequentially expanding species distribution towards unoccupied grid cells that are adjacent to those already occupied by the species, until the predefined range size is reached. The process iterates until all species are "spread" in the domain, and the entire procedure is then replicated to estimate the expected mean and variance of species richness per cell. This algorithm has been widely used by macroecologists, and has also served as the basis for more complex and advanced models that incorporate multiple interacting mechanisms, such as evolutionary niche dynamics, speciation, extinction, and range fragmentation. In their original work, Jetz and Rahbek (2001) showed that the pattern of species richness expected under the spreading dye model is somewhat similar to the observed pattern of African bird richness.

As is usual for the most innovative ideas, the MDE sparked a vigorous debate among biogeographers. The validity of MDE as a model for gradients of species richness was challenged on both empirical and conceptual grounds (Hawkins and Diniz-Filho, 2002; Zapata *et al.*, 2003), followed by a point-by-point response to arguments against the MDE (Colwell *et al.*, 2004, 2005; Jetz and Rahbek, 2001). Regardless of the best design for a model that is "null" with respect to the influence of environmental factors, and of the validity of geometric constraints as a significant driver of biogeographical patterns, biogeographers realized that a simulation framework was a useful approach to be included in their research toolboxes (Gotelli *et al.*, 2009).

Pushing forward the simulation approach, many authors developed new, spatially explicit stochastic models to explain spatial patterns in species richness at continental scales. As a consequence of a growing emphasis on exploring the mechanisms behind species distributions, while taking account of

constraints, contingencies, and chance events, these authors pioneered the incorporation of environmental factors known to affect species richness, along with stochastic effects, such as dispersal and centers of origin. The core idea behind such models is that, rather than correlating species richness with environmental or evolutionary factors directly, these factors are incorporated into the simulation framework following the hypothesized mechanism. In addition, because species distributions are explicitly simulated, the model yields predictions in units of species richness per location. The spatial pattern in species richness predicted (expected) by simulation models can be compared against empirical (observed) patterns found in nature as a measure of model fit. Comparing explanatory power among different simulation models is a straightforward statistical task, especially when compared with correlative and curve-fitting model strategies (see Gotelli *et al.*, 2009 for a review).

In an early contribution to this literature, Bokma *et al.* (2001) designed a simulation model to study how species would be distributed over irregularly shaped domains under a purely stochastic process. Their study promoted a significant conceptual advance in biogeographical models by incorporating several spatially explicit mechanisms that are known to affect patterns of biodiversity, such as speciation, migration, and extinction. They found that when these mechanisms occur at random over space, the predicted pattern of species richness must also be random. However, if species migration is constrained by space, and speciation and extinction are also spatially patterned, their model predicts that the center of major landmasses should have higher species richness. However, the model predictive power of real-world pattern of species richness of New World mammals was always very poor, regardless of how the biogeographical mechanisms incorporated in the model were parameterized.

To explore the role of phylogenesis in range-based models on a bounded domain, Davies *et al.* (2005) developed a simple, stochastic model of the origination and spread of a clade in two-dimensional space (a 100×100 grid). They showed that the spatial pattern of richness across the domain (once 500 species have arisen) depends crucially on (1) phylogenetic conservatism of range location (ranges either split peripatrically, *in situ*, or split and one of the two daughter species is then placed at random within the domain) and (2) asymmetry (imbalance) of phylogenetic trees (parameterized by setting the degree of heritability of speciation rate). With random placement of daughter ranges, with or without tree asymmetry, a classic mid-domain peak of species richness (MDE pattern) arises, as expected. However, when range location is conserved, the MDE pattern is somewhat weakened. Finally, when tree asymmetry is allowed and range location is conserved, the MDE pattern is no longer evident and location of richness peaks becomes increasingly idiosyncratic, suggesting that the MDE is an appropriate ecological null model only when phylogenetic influence on range location is known to be low or nonexistent.

Taking a different perspective, and explicitly modeling the effect of environment on the distribution of species, Rangel and Diniz-Filho (2005a) designed a spatially explicit simulation to model speciation, range expansion, extinction, and species richness on a simple environmental gradient. In

their model, the one-dimensional domain is a bounded grid, which is divided into equal-sized cells. Along this transect, a linear environmental gradient is established by assigning a “suitability” value to each cell, with suitability increasing linearly from one end of the transect to the other. The difference in suitability between the least and most suitable cells, at the ends of the spatial domain, determines the steepness of the gradient, and defines the limits of the single axis of niche space.

In the model of Rangel and Diniz-Filho (2005a), an initial species is seeded at a location (cell) along the gradient that is chosen as a stochastic function of environmental suitability, so that a cell toward the more suitable end of the gradient is more likely to be chosen than a cell towards the less suitable end. The value of environmental suitability of the seed cell is defined as the niche center of the species, and a symmetrical niche deviation around the niche center (environmental tolerance) is stochastically defined from a normal distribution. The range of values between maximum and minimum environmental tolerances determines the range of environmental conditions that can be tolerated by the species (its niche breadth), and thus, the boundaries of its niche space. Once the niche is defined, it is projected back onto the geographic space, and the species spreads its geographic range into all suitable cells (all map cells inside its niche, in niche space). The model algorithm iterates in time, and at each step in time, each existing species may speciate (with a specified speciation probability). In the event of speciation, a cell at the periphery of the parent species’ range is chosen as the seed cell for a daughter species, as a stochastic function of environmental suitability, so that a cell towards the more suitable end of the range is more likely to be chosen than a cell towards the less suitable end. The environmental condition of the cell where the daughter species arises becomes its niche center, a new niche breadth is sampled from the same normal distribution, and the new species colonizes all adjacent cells in which the environmental factor lies within its niche.

As opposed to the conventional prediction that the peak of species richness should always occupy the most “suitable” region of the domain, in the model of Rangel and Diniz-Filho (2005a) the pattern of species richness depends crucially on the strength of the environmental gradient. In their model, a strong and steep environmental gradient forces species to have small ranges, given their environmental tolerances, and the evolutionary dynamics promotes higher extinction in the less suitable region of the map, therefore promoting high species richness in the region of highest environmental suitability. However, as the strength of the environmental gradient weakens, the average and variance of species range size become larger, and thus species increasingly overlap in the middle of the domain as a consequence of geometric constraints on the range location. The richness peak gradually shifts toward the center of the domain as environment weakens, until, at the limit, the MDE disappears entirely with the absence of environmental gradient, when the model predicts flat pattern of species richness. The model of Rangel and Diniz-Filho (2005a) provides support for the view of geometric constraints as a mechanism driving species richness in relatively uniform environment, with well-defined boundaries.

Storch *et al.* (2006) and Rahbek *et al.* (2007) adapted the spreading dye model to incorporate the influence of environmental factors on the distribution of species. These authors realized that the bounded surface in which the dye spreads is never homogeneous. In fact, the real-world variation of environmental factors across space, as well as the interaction among these factors at different spatial scales, creates habitats that differ with respect to suitability. According to the algorithm independently designed by those authors, species should have higher probability of expanding their distribution towards regions with “more suitable” environment, including warmer and wetter areas known to harbor higher species diversity. In addition, they also relaxed the assumption of range cohesion, and evaluated how different degrees of long distance dispersal could affect the predictive power of those models. Storch *et al.* (2006) evaluated how such a model could predict global patterns of avian diversity, and found that best predictions are achieved when the probability of a range spreading into an area is directly proportional to the AET of the area. Rahbek *et al.* (2007) studied the pattern of species richness of birds in South America, and also showed that model predictive power increases when (i) water–energy environmental factors affect species range expansion, (ii) range cohesion is imposed in the model algorithm, and (iii) only large-ranged species are considered. Perhaps the single most important conceptual advance in those models was moving beyond the debate on the best null model for spatial patterns in species richness by directly incorporating ecological “mechanisms” into the model algorithm (Gotelli *et al.*, 2009).

A natural next step for simulation models in biogeography was to add more realism, and more complexity, by replacing the static environmental gradient of the previous models by a heterogeneous, multivariate, and fluctuating environment. Of course, the complexity of species’ niches must also be incorporated, by adding the corresponding dimensions of species environmental niche, which are continuously responding to evolutionary forces and interacting directly with the fluctuating environment. As in previous models, Rangel *et al.* (2007) treated geographic space as defined as a spatially bounded set of square grid cells on a plane. Each cell was characterized by an array of environmental variables, which collectively defined a spatially heterogeneous pattern within the geographic space. In this model, a “seed species” colonizes a randomly chosen grid cell on the map, and the environment in that cell defines the niche center of the seed species in niche space. The species is assigned a niche breadth, stochastically from a normal distribution, separately for each environmental niche axis, and the species’ geographical range is then defined by projecting its niche volume back into the geographic space to fill all contiguous cells around the seed cell that map inside the niche volume, so that ranges are always in equilibrium with environment.

In this simulation (Figure 3), the environment is not constant through time, but fluctuates sinusoidally. Because each species’ geographic distribution is an interactive consequence between its niche (defined by tolerance range for each environmental variable in niche space) and the geographic space (actual environmental conditions on the map, which change through time), environmental fluctuations may

cause contraction, expansion, reshaping, or fragmentation of the species’ geographic distribution. Range fragmentation may yield vicariant speciation: each isolated “population” (range fragment) may go extinct as function of its size, or it may speciate and become an independent new species. Each incipient daughter species inherits its parent species’ niche center, but with a specified degree of adaptive evolution permitted. Adaptation moves the niche, through niche space, toward the average environmental conditions of the daughter species’ geographic distribution, which in general will differ from the average environment of its parent species. Adaptive shifts in daughter species’ niches in niche space are projected back onto the geographic space to reshape ranges accordingly. The niche breadth of the daughter species is also inherited from the parent species, although the daughter species’ niche breadth can be stochastically broadened or narrowed. In this model, niche conservatism is simulated when a daughter species inherits parent species’ niche center and niche breadth without much change, whereas niche evolution implies adaptation of the daughter species’ niche center towards its own local environmental conditions, and increase or decrease of niche breadth (Figure 3).

Rangel *et al.* (2007) used the model to show how the interplay between evolutionary niche shifts and fluctuating environment drives broad scale pattern in species richness. When model parameters are set to strong niche conservatism, species cannot readily adapt to local environmental conditions, and thus they accumulate in regions that are environmentally similar to those occupied by their ancestors. Because of the spatial autocorrelation in the environmental factors, the geographic region of highest diversification rates tends to be closer to the location where the lineage arose. In contrast, if model parameters allow niche evolution during speciation events, species niches readily evolve through niche space, allowing descendent species to exploit environmental conditions that were unsuitable for their ancestors. In this case, the geographic distributions of descendant species tend to be different in size, shape, and location compared to the distributions of their ancestors. Of course, this model shows that niche evolutionary dynamics and center of origin strongly affect spatial patterns in species richness if the temporal dimension is included in the model. Rangel *et al.* (2007) designed an empirical test of the model by contrasting the model predictions against real-world patterns of species richness of South American birds, and they found that the model has very high predictive power when center of origin is tropical and niche conservatism is strong. This was the first attempt to use an explicit evolutionary model to investigate how species richness patterns are influenced by niche conservatism (Wiens and Donoghue, 2004). In fact, their simulation allowed evaluation of the roles of both evolutionary and ecological processes, revealing the great potential of the link between ecology and historical biogeography under integrated theoretical and methodological frameworks.

Recently, Colwell and Rangel (2010) applied a similar stochastic simulation model to study how quaternary glacial–interglacial temperature cycles affected contemporary geographical and phylogenetic patterns of species richness along tropical elevational gradients. In their model, key ecological and evolutionary mechanisms are explicitly simulated,

Figure 3 The stochastic model proposed by Rangel *et al.* (2007), in which species are subject to range expansion, displacement, fragmentation, extinction, speciation, and niche evolution in a spatially complex and fluctuating environment (South America). (a) Geographical ranges of two hypothetical, ancestral species (red and blue areas), defined by their respective environmental niches, projected into the geographic space. The environmental factors that characterize the map are subjected to fluctuation, which causes (b) range fragmentation (red and blue areas, solid outlines), with variable fragment size. (c) Smaller fragments go extinct as a stochastic function of their geographical extent (light red and blue areas, dashed outlines), whereas larger fragments survive (dark red and blue areas, solid outlines) as the initial distributions of daughter species. (d) After speciation, evolution of the niche of each new species is modeled in niche space (not shown), with a specified degree of niche conservatism. The geographical distribution of each descendant species is a function of its evolved niche, adjusting the size and placement of its geographical range (original fragments are shown as white areas, dashed outlines) to colonize contiguous areas in the geographical space (colored areas, solid lines) that correspond to its new ecological niche.

including speciation, anagenetic evolution, niche conservatism, range shifts, and extinction. Their models suggested that elevational patterns of species richness arise from the differential survival of founder lineages, consolidated by speciation and the inheritance of thermal niche characteristics. The model yielded a surprisingly rich variety of realistic patterns of phylogenetic and species richness, including some that closely match contemporary elevational richness profiles from an elevational transect in Costa Rica, which were chosen for the wide variety of elevational richness patterns that they represent.

Directions and Future Work

Biogeographical models that strictly rely on the correlative approach are problematic because most such models do not make quantitative predictions. In fact, the application of these models to the study of biogeographical patterns usually leads no further, once the researcher has qualitatively described a

good match between spatial patterns in species richness and some measures of contemporary climate. Owing to the lack of *a priori* expectations, parameters estimated by such models are commonly left with little or no biological interpretation. The dynamic nature of evolutionary processes through time is usually left out of the model, although no biogeographer would reject historical factors, such as climate fluctuation, speciation, and extinction as important drivers of the biogeography of living organisms. As noted by Currie *et al.* (2004), most correlative models are not founded on solid theoretical principles of ecology and evolutionary biology, nor do they incorporate biogeographical mechanisms thought to affect the distribution of species. In fact, they are so vaguely specified that they do not predict anything more precise than a high correlation between species richness and measures of contemporary climate. However, for practical reasons, it will be difficult to totally abandon correlative models, so efforts must be made to better define surrogates for the multiple hypotheses, especially for dealing with evolutionarily dynamic mechanisms, such as niche conservatism and geographically

structured diversification rates. To employ correlative models to test niche conservatism as a mechanism for patterns of species richness, it is important to incorporate in the analysis the phenotypic traits that may be linked to the emergence and maintenance of these patterns, which may be under stabilizing selection processes that constrain the dynamics of geographic ranges through time. Of course, when the evolutions of species traits are taken into account in biogeographical studies, the full scope of analytical methods from phylogenetic comparative analysis should be considered as the first resource (e.g., Hof *et al.*, 2010). It is also important to implement better designs for correlative studies of patterns in species richness, especially with regard to multiple geographic scales, both in terms of grain size and geographical extent.

Correlative models that are designed based on theoretical first principles provide quantitative predictions that can be contrasted against real-world patterns. Models of this category are still in their infancy, as the biological mechanisms at lower organizational scales (from molecules to populations) that affect broad scale ecological patterns are not well understood. However, such models may nonetheless bring a dramatic conceptual improvement over correlative models, pushing biogeography towards a more precise definition of patterns, mechanisms, and scales. As pointed out by Cassemiro and Diniz-Filho (2010), there is still room for improving the models designed under the Metabolic Theory of Ecology that are applied to richness gradients, especially regarding the incorporation of more complex macroecological patterns (i.e., geographic variation in body size and abundance) to avoid critical and potentially unrealistic assumptions, such as energy equivalence in ecological communities. The challenge is, obviously, to derive a mathematical prediction of how these additional factors act, in concert and interacting with other mechanisms, to drive ecological patterns from the bottom up.

In contrast with correlative modeling approach, simulation modeling has the potential to explicitly incorporate the processes believed to be affecting the geographical ranges of species. In principle, simulation models can be designed to test specific ecological mechanisms. However, general simulation models are usually preferred because they incorporate multiple interacting mechanisms, and can be both temporally and spatially explicit. Of course, the more the mechanisms incorporated in the model, the more complex the model becomes, and therefore testing and validating the model may become cumbersome. However, the cost of the additional complexity in the model could be balanced, in principle, by a wide array of quantitative predictions that can be compared against empirical patterns during model validation, providing a more robust evaluation of model predictive power. No doubt, the use of simulation models in biogeography is still in its infancy, and so are the statistical techniques available for model test and validation. Gotelli *et al.* (2009) have proposed a measure of goodness-of-fit, along with a corresponding hypothesis test, to evaluate the predictive power of simulation models with regard to patterns of species richness. However, simulation models in biogeography are evolving fast, and models are now extending their predictions to the new aspects of biodiversity patterns, such as the evolution of functional trait diversity (Stegen and

Hurlbert, 2011), which thus requires better empirical data and the development of additional statistical techniques to measure model predictive power.

Levins (1966), in his influential paper on “the strategy of model building in population biology,” pointed out that “the difference between legitimate and illegitimate (model) simplifications depends not only on the reality to be described but also on the state of the science.” Although biogeography is not a young science (Lomolino *et al.*, 2009), the complex and heterogeneous nature of the phenomena that biogeographers struggle to understand slows down the pace of conceptual progress, as well as the development of models with higher predictive power. Still, the strategies of model building laid out by Richard Levins 45 years ago are also applicable to biogeography. According to him, “it is of course desirable to work with manageable models which maximize generality, realism, and precision toward the overlapping but not identical goals of understanding, predicting, and modifying nature”. The balance and emphasis on each of these three goals is reflected in the modeling approaches used by biogeographers:

1. Sacrificing precision and realism for the sake of generality. Within this category are the correlative models that are empirically oriented, which are mainly concerned with qualitative rather than quantitative results. Hypothesis testing or theoretical interpretation of estimated parameters is usually not the focus of studies that employ this approach. Instead, the form and direction of the relationship between species richness and each environmental factor is described. Predictions can rarely be drawn based on these models.
2. Sacrificing realism and generality for the sake of precision. Correlative models that are derived from ecological principles fall within this category. These models yield precise predictions on how species richness is affected by the hypothesized factor. One of the main advantages of these models is that their predictions can be tested and validated using robust statistical methods, and if the model is considered reliable enough, it can also be used to project species richness into an area outside the range of environmental values. Derived correlative models vary with regard to the level of generality they incorporate, but certainly the more general they are, the less precise they become.
3. Sacrificing generality and precision for the sake of realism. Stochastic simulation models are arguably the most “mechanistic” and “realist” models used by biogeographers, but their predictions are less precise and usually more general than correlative models. One of the main advantages of the simulation approach is to make explicit assumptions about how the processes believed to be affecting the distribution of species operate. The drawback of this approach to modeling is that the realism comes at the cost of additional free parameters, which are not straightforward to quantify or parameterize. Also, documenting and communicating the entire model algorithm is not a trivial task, a challenge that has motivated some authors to suggest a standard protocol for describing agent-based models (Grimm *et al.*, 2005).

Finding the optimal balance between model simplicity and complexity is not a trivial task, but should be considered as a central problem in biogeographical modeling. The principle of parsimony suggests that when choosing a modeling approach, a simpler model should always be preferred, unless simplicity can be traded for increased explanatory power. On one hand, a model that is too simple tends to ignore important mechanisms known to affect the real system, which would limit its potential to provide scientific understanding and testable predictions. On the other hand, despite the higher predictive power of complex models, the analysis of a model that is too complex tends to be cumbersome, potentially risking the advance of understanding of the problem it addresses. The famous quote from George E. P. Box is particularly true for biogeographical models: “essentially, all models are wrong, but some are useful”.

Glossary

ALS Amyotrophic Lateral Sclerosis, a devastating paralytic disease known in Europe as motor neuron disease and in North America as Lou Gehrig's disease.

AMPA-kainate receptors Glutamate receptors often found in motor neurons.

Archaea Nonbacterial microorganisms that often live in extreme environments, comprising (in addition to eukarya and bacteria) the third domain of life.

Biomimetics An artificial compound, device, or structure that mimics or was inspired by nature.

Denticles Small tooth-like projections such as those that occur on shark skin.

DNA fingerprinting Techniques used to amplify small amounts of DNA to identify individuals, often for forensic purposes.

Extremophile An organism that lives and thrives in a habitat characterized by extremes of temperature, acidity, alkalinity, salinity, light, or pressure that would prove lethal to most other organisms.

Herbal A book recording accumulated knowledge of medicinal plants.

Indigenous knowledge Traditional understandings of villagers which are often orally transmitted from generation to generation.

Patent Government grant of the right to inventors to exclude others for a period from manufacturing or selling an invention.

Bioprospecting refers to the assessment of life forms for development of unique molecules, biological entities, or structures that have potential utility in the economic sphere. Examples of bioprospecting include the screening of microorganisms for the ability to metabolize oil spills, the screening of marine organisms for antifouling compounds to prevent the attachment of barnacles to ship hulls, the analysis of archaeal species in hot springs to discover new temperature resistant DNA polymerases, or the search for new pharmaceutical compounds from rain forest plants for the treatment of disease.

Commercial Development of Biodiversity

Although the term bioprospecting is often used in the press to characterize the search for commercially viable new molecules, genomes, and structures from nature, the imputed analogy to destructive, extractive enterprises such as mining is incorrect because the biological resources are not typically consumed or destroyed during the development process. Thus bioprospecting is considered by many scientists to be a pejorative term that does not properly describe the recourse to nature that is being increasingly used to generate important new discoveries. Although bioprospecting programs have been successfully used to discover new agriculturally useful compounds such as herbicides and insecticides, the development of new or improved agricultural cultivars or livestock animals is typically not considered to be a bioprospecting activity. Implicit in a bioprospecting exercise is the goal of discovering a novel molecule, biological structure, or development of a unique genotype which can, in theory, be produced in the

laboratory, rather than be gathered from nature. If replicable synthesis of the molecule or genotype cannot be produced in the laboratory due to molecular or genetic complexity, laboratory extraction of the useful entities from agricultural production is employed. In the absence of such repeatable synthesis or process, the commercial requirements for dependable sourcing and intellectual property protection are unlikely to be achieved. Unlike unsustainable wild harvesting that sometimes occurs in the herbal trade, bioprospecting programs are firmly rooted in biological conservation. When successfully conducted, bioprospecting may better be termed "sustainable development from nature" particularly in biodiverse-rich countries which share the cultural, educational, and financial benefits of discovery.

History

Ethnobotanical and ethnozoological studies document an awareness of the natural world by indigenous peoples that many individuals resident in industrialized countries would find remarkable. For example, in the late 1920s, evolutionary biologist Ernst Mayr was surprised to discover that villagers in New Guinea had names for all of the bird species that he collected. "I realized that every bird the natives saw and that they had shot, they knew the name. So I recorded that Latin name that I knew and the names the natives gave me . . . I found that I had in this locality collected 137 species of birds, and the natives had given me the names of 136 of these." In Samoa, villagers have names for over 46 different breadfruit cultivars (Ragone *et al.*, 2004). Indigenous names are typically

binomials that often describe salient features or useful properties of the plants and animals in their environment.

Although usually transmitted orally, traditional knowledge of biodiversity was sometimes compiled in early herbals and bestiaries, including useful aspects of different species. Gerard's *Herball* of 1597 includes a description of the pharmacological efficacy of *Digitalis purpurea* (Scrophulariaceae): "Foxe glue boiled in water or wine, and drunken, doth cut and consume the thicke toughness of grosse and slimie flegme and naughtie humours; it openeth also the stopping of the liver, spleene and milt and other inward parts." The development of digitalis as a crude drug for the treatment of congestive heart failure awaited further investigations by William Withering in 1785. Today, over 1500 kg of digoxin are prescribed to heart patients throughout the world. A total of 18 different pharmaceuticals, including 16 used today have been derived from Gerard's *Herball* (Cox, 1998). Indigenous observations of animals have also yielded extraordinary uses. For example, in Sweden, certain species of snails were used to lubricate the axles of wagons, while the viscera of fugu puffer fish (*Fugu rubripes*) in Japan was found to produce in individuals eating the fish an unusual and potentially dangerous tingling of the tongue and lips due to the presence of tetrodotoxin. Similarly, the hairs of the velvet bean *Mucuna pruriens* (Fabaceae) in Africa were used to tip poison arrows in Nigeria and as a murder drug in Senegal due to the presence of serotonin and its analogs including dimethyltryptamine and 5-methoxydimethyltryptamine. This same plant yields levodopa, a powerful drug used in the treatment of Parkinson disease. More recently, Eric Buenz and his colleagues at the Mayo Clinic have referenced the *Herbarium Amboense*, an early eighteenth century compilation of botanical knowledge from Indonesia by Rumphius, as a source of discovering new pharmaceuticals (Buenz et al., 2004).

These discoveries exemplify the often serendipitous nature of discovery of useful products from biodiversity, a process that has been accelerated with the rise of modern science.

Targets, Screens, and Structural Determination

Historically, most innovative uses of biodiversity have been based on serendipity rather than on a systematic approach to discovery such as those used in modern bioprospecting programs. Often nature, which through evolutionary time has provided solutions to physical and biological challenges, is referenced by scientists in the search for novel solutions to physical or medical problems. Sometimes systematic searches for desired properties or entities from nature are carried out. Regardless of the scale and complexity of the search, three components typically compromise modern analyses of nature for new commercial uses: (1) a target of desired physical, biological, or molecular activity, (2) a screen to determine if a particular species or biological sample possesses the desired activity, and (3) isolation, the attempt to remove the desired activity from the species or sample in order to employ it in other settings. Such searches can be a single reference to nature for inspiration, others can involve multiple, iterative approaches to biodiversity. Because screening and isolation strategies are similar for many new entities from biodiversity,

it is perhaps useful to categorize bioprospecting programs not on their process, but instead on their targets. These targets can be divided into those used to discover useful entities for agriculture (e.g., herbicides and pesticides), biomimetics (such as velcro), diagnostic procedures (e.g., the development of new enzymes for DNA fingerprinting), disease prevention (e.g., antiseptics, molecules to control disease vectors), environmental remediation (such as removal of consumer waste, oil spills, and toxic mine tailings), genetic analysis (e.g., discovery of new structural and regulatory gene sequences of commercial value), new materials (including antifouling compounds for ships, dirt resistant paints for houses, etc.), and the discovery of new pharmaceuticals (e.g., antibiotics, anticancer compounds, treatments for chronic pain, etc.). Given the extraordinary molecular diversity of life on earth, novel uses of biodiversity will only increase through time as both innovation and scientific techniques for biodiversity analysis continue to increase. Thus, this list of targets should be seen as illustrative rather than comprehensive.

Insecticides, Pesticides, and Herbicides

Fish Poisons as Insecticides

In the islands of Samoa, reef fish are sometimes harvested by the use of plants which have a chemical agent that stuns them. Both *Tephrosia patula* (Fabaceae) and *Barringtonia asiatica* (Barringtoniaceae) are used as fish poisons (Cox, 1979). The roots of *T. patula* are macerated and placed in a leaf bundle which is immersed in the shallow reef, while the seeds of the box-like *B. asiatica* fruits are scraped into tidal pools. After about five minutes, the stunned fish rise to the surface and are gathered in woven baskets. The poison does not affect the edibility of the fish. *B. asiatica*, known in most Polynesian languages as "futu" is used throughout the southwest Pacific, while in Melanesia a legume related to *T. patula*, *Derris elliptica* is known in some languages, such as the Geri language of Guadalcanal, as "vutu." Obviously, this term refers to use rather than taxonomic affinity. Chemically, the active agent in all of these fish poisons is rotenone, originally discovered in 1895 by Emmanuel Geoffroy from *Lonchocarpus nicou* (Leguminosae) used by villagers in Guyana to capture river fish.

Fish and some insects, such as parasitic mites on chickens, are exquisitely vulnerable to rotenone since it is quickly absorbed through gills and trachea. It is of low toxicity to mammals, including humans, since it is absorbed only slowly through the gastrointestinal system. Rotenone has been used to kill a variety of garden pests, and since it is biodegradable, has only a short window of toxicity. There is some concern that rotenone use may be linked to Parkinson disease in farmers.

Neem, A Natural Insecticide

The neem tree of India, *Azadirachta indica* (Meliaceae), is considered to be one of the world's most useful trees since it provides shade, fuel, fodder, and an extremely important insecticide, Azadirachtin (National Research Council, 1992). For centuries, villagers in India have placed the leaves and branches of the neem tree in granaries and pantries where it serves to actively deter feeding by insects. The active compound,

azadirachtin, is a potent inhibitor of the insect hormone ecdysone and interferes with metamorphosis and molting. At concentrations as low as 10 ppm, it is lethal to moth and butterfly larvae.

One of the promises of neem is its insecticidal efficacy as a crude extract or even as dried plant materials, particularly since azadirachtin is biodegradable. It therefore is suitable for exploitation as an insecticide by the poorest of the poor as well as by major agribusiness industries. In a remarkable case of parallel chemical discovery by indigenous peoples from different continents, the leaves of the Chinaberry tree, *Melia azedarach* (Meliaceae), were used by the Cherokee and Navajo tribes to keep insects away from their homes.

The potency of neem as an insecticide led several multinational agricultural firms including W.R. Grace to seek patent protection for pesticides derived from neem. However, in May 2000, the European Patent Office revoked a patent granted for a neem-based fungicide. The patent rejection responded to a challenge by Vandana Shiva of the India-based Research Foundation for Science, Technology, and Ecology, who argued that the patent was based in part on prior art, for example, folk uses of the plant.

Antifungal Crop Treatments

Higher plants fight an ongoing chemical battle against fungal hyphae that are ubiquitous in the environment and which quickly infect new plant growth. Extracts of the broad bean, *Vicia faba* (Fabaceae), were found to have potent antifungal activity. This activity was initially attributed to a natural acetylene, wyerone, by Fawcett at the University of London. Further studies led to the identification of a reduced form of wyerone, a phytoalexin, as an even more active component. Wyerone is important because it demonstrates wide spectrum activity against many fungal pathogens and has been successfully tested on a variety of crops.

Biomimetics

Velcro, An Alternative Fastener

Velcro, developed for the US space program, was invented in 1941 by Swiss Engineer George de Mestral, who lived in the village of Commugny near Lake Geneva. He was fascinated by the spiny fruits of burdock plants (*Artium tomentosum* (Compositae)) and the way they adhered to his clothes and his dog's fur. Fruits which are dispersed by adherence to the fur or feathers of their unwitting vertebrate hosts are termed to be epizoochorous, and often are equipped with mechanical or chemical adhesives that allow them to be carried long distances. Under the microscope de Mestral noticed that the hooked hairs of burdock fruits ensnare loops of fabric or hair. He realized that a similar pattern of hook and loops could be used to attach different objects together. In his Swiss patent of 1951 and his US patent no. 2,717,437 in 1953 entitled, "Velvet Type Fabric and Method of Producing Same," de Mestral diagramed a hook and loop arrangement for attaching fabrics that was later trademarked as Velcro. In the search for effective fasteners that are impervious to temperature and which cannot freeze nor be fouled like zippers, Everest climbers quickly sought to have Velcro as a backup fastener on their down

parkas and trousers. Eventually, Velcro became an important product for astronauts who work in zero gravity. During space missions, Velcro is used to hold down tools, tablets, pens, and other instruments.

Self-Cleaning Lotus Paint

The lotus plant, *Nelumbo speciosa* (Nelumbonaceae), is sacred to three different major world religions. Lotus is considered in the Hindu faith to have sprung from the navel of Lord Vishnu. The rhizomes are boiled in China, Japan, and other Asian countries as a delicacy, and the young leaves are eaten as a vegetable. A remarkable feature of fresh lotus leaves, known to small children, is the inability of the leaves to be wetted. A droplet of water placed on a lotus leaf assumes the appearance of a drop of mercury placed on a glass pane. By swiveling the leaf, the water drop can be spun about the leaf surface like a ball bearing without diminishing in size. Microscopic examination of the leaves reveal a pubescent, rather than smooth surface, with numerous small hairs spaced at a distance smaller than the diameter of a small water drop. The water drop is in essence held aloft by these hairs which allow only 2–3% of the surface area of the water drop to contact the leaf surface. As a result, lotus leaves are self-cleaning, and the slightest vibration in calm morning air causes condensed dew to roll down into the center of the leaf.

These features of the lotus leaf were observed by Wilhelm Barthlott, Director of the Botanical Gardens at the University of Bonn, Germany, who was inspired to create a self-cleaning paint based on the lotus leaf effect. Marketed by the German company STO as LotusanTM, these hydrophobic paints cause water to bead so that mineral, cement, and concrete surfaces painted with them are self-cleaning. Not only does this hydrophobic paint prevent dirt and grime from accumulating, but it also reduces attachment of algae, bacteria, and fungi to buildings in damp and dirty environments.

Architecture Based on Termite Mounds

Designers and architects have studied and utilized the incredibly strong and beautiful designs in natural forms for centuries. The Spanish architect Antoni Gaudi utilized many nature-inspired forms in his buildings in Barcelona, Spain. Among his most famous projects, the Familia Sagrada Church, contains numerous forms from nature, even though the building was only 25% completed at the time of his death in 1926. The church contains tree-like pillars that support the roof in several sections and in the basement of the Familia Sagrada there is an exhibit demonstrating the connection between the forms of trees, shells, leaves, and other forms found in nature in this building that is still under construction in 2011. Similarly, the Sydney Opera House, while considered to be an expressionist modern design by Danish architect Jørn Utzon, is composed of four large precast concrete shells that resemble cockle shells attached to a rocky marine coast.

Another example of architecture inspired by nature is the Eastgate Centre in Harare, Zimbabwe. This building, designed by architect Mick Pearce, has no conventional air conditioning or cooling systems but still maintains a regulated temperature year round. This is achieved in part by mimicking the self-cooling mounds – some which are 9 m tall – built by African termites. The mounds are passively thermo regulated

to maintain a temperature of 31 °C in savannah environments where external temperatures vary from 2 °C at night to 40 °C in the daytime. Such exquisite temperature regulation is required for cultivation of the fungus the termites depend on. Compass termites of the genus *Amitermes* build their mounds with the long axis oriented north to south, and which have a series of heating and cooling vents throughout the mound. The termites are constantly digging new vents and plugging up old ones as part of the process to regulate the temperature, thus generating a series of convection currents that moves air up and down. By mimicking these termite mounds, the Eastgate Centre uses less than 10% of the energy of a conventional building of the same size. This nature-inspired design saved the owners of the building more than \$3 million in construction costs.

Gecko Tape

Many visitors to Polynesia have been amazed by the ability of geckos of the genus *Lepidodactylus* to climb upside down on the rafters of village huts, or the ceilings of hotel rooms. Suspended upside down, the geckos chirp to attract mates and capture unwary insects. The ability of geckos to adhere to even smooth surfaces is produced by countless rows of small setae, tiny hair-like projections on their toes. The density of these structures on the gecko footpad is approximately 500,000 per mm. Each setae then branches into hundreds of patula of 100 nm length. Lacking an electrical charge, these projections from the gecko footpad are attracted to surfaces with a small charge by van der Waals forces. This attraction is so strong that geckos walk by curling their toes for attachment and subsequent peeling.

Engineers have attempted to duplicate this approach by producing tiny nanofibers which can attach to a substrate. Andre Geim, a Nobel Prize winning physicist at the University of Manchester, UK, has been adapting the principles of gecko acrobatics to produce gecko tape, which can be used to allow robots to climb cliffs or difficult surfaces, and which may provide new surgical adhesives.

Shark Swimsuits

Predatory sharks, such as the Great White sharks off the coast of northern California, need to move with speed and agility through the marine environment to capture highly predator-averse marine mammals. They are facilitated in their speed by skins with tiny tooth-like scales called denticles that significantly reduce hydrodynamic drag as they swim through the water.

Amy Lang at the University of Alabama, USA, discovered that sharks that swim at high speeds have smaller denticles than shark species that swim at slower speeds. Her data have indicated that the denticles of faster sharks, much like the dimples on golf balls, “bristle” as they swim creating a distinct surface pattern which significantly reduces hydrodynamic drag.

This feat of evolution has profound implications for aircraft and boat design. Reducing the overall drag on large vessels by 1 or 2% can result in huge energy savings in fuel. Swimsuit design has also been influenced. Swimmers at the Beijing Olympic Games used FS11 “fast swimsuits” that mimic some of the morphology of shark skin to enhance their ability

to move through the water with minimum resistance (Eadie and Ghosh, 2011).

Diagnostic Procedures and Techniques

Litmus Paper

Lichens were discovered as useful indicators of acidity by the French chemist Gay-Lussac in the early nineteenth century. The word “litmus” is derived from a Middle English term *litemose* related to the Old Norse term for dyer’s herbs *litmosi* (dyer’s herbs *lit* + *mosi* moss). Lichens including *Roccella tinctoria* (Roccellaceae) from the Mediterranean and *Lecanora tartarea* (Lecanoraceae) from The Netherlands are combined with wood cellulose to manufacture litmus paper. Under neutral conditions, the paper is purple, but turns red in the presence of acids and blue in the presence of bases. While unsuitable for titrations, litmus paper is still used today for rapid assessment of the acidity of environmental and laboratory samples.

Lichens as Air Pollution Monitors

It has been long known that lichens – symbiotic organisms composed of a fungal and an algal or cyanobacterial partner – are exquisitely sensitive to air pollution, probably because they rapidly absorb chemicals from air and water. The nature of the symbiosis means that when the most vulnerable partner to the pollutant is damaged, the symbiosis is destroyed and the lichen dies.

Since lichen species vary in their sensitivities to different pollutants – heavy metals such as lead, zinc, or copper; ozone, hydrocarbons, or acid rains – surveys of lichen species present in a city or near a mine can give a good indication of air quality. Such lichen surveys can be compared to historical surveys of the same area or compared to the lichen floras of nearby regions with pristine air. In northern Sweden, Mats Karström has developed an innovative system for assessing forest quality merely by surveying the lichen flora.

The long filamentous strands of Methuselah’s Beard lichen (*Usnea longissima* (Parmeliaceae)) were once used in Europe as tinsel on Christmas trees. But now this lichen, which was once the source of the antibiotic usnic acid, has largely disappeared from industrial areas of Europe where air quality has been compromised. Lichen surveys based on a 10-point scale for sulfur dioxide concentrations were used as early as 1977 by David Hawksworth at the University of Gloucestershire, UK, and Francis Rose at Kings College, London, to map air pollution levels in England, Wales, and Ireland. More recently, Larry St. Clair and his son Sam at Brigham Young University, USA, have used lichen tissues from the Chiricahua National Monument in Arizona as passive filters for the quantification of copper levels in the air.

Green Fluorescent Protein from Jellyfish

In 2008, the Nobel Prize in Chemistry was awarded to Osamu Shimomura, Martin Chalfie, and Roger Tsien for development of the green fluorescent protein (GFP) from the jellyfish *Aequorea victoria*. As a scientist at Princeton University in 1960, Shimomura began studies of bioluminescence in the jellyfish. From specialized organs, jellyfish release calcium ions to the

protein aequorin which glows with blue photoluminescence. This blue light is then absorbed by GFP, which in turn fluoresces green. In 1987, Douglas Prasher at Woods Hole Oceanographic Institution realized that if the genes for GFP were inserted before the stop codon into the genes for any other protein, they could function as a fluorescent tag. In 1992, Prasher cloned the 238 amino acid protein from the jellyfish and in 1994 sent it to Martin Chalfie at Columbia. Chalfie later said about Prasher, who was left off of the Nobel Prize citation, that his "work was critical and essential for the work we did in our lab. They could've easily given the Prize to Douglas and the other two and left me out." Chalfie gave the GFP clone to his graduate student Chia Euskirchen who inserted it into *E. coli* bacteria. The bacteria were found to fluoresce green under UV light. Subsequently, Roger Tsien and colleagues at the University of California, San Diego, discovered how GFP works, and produced a variety of mutants that fluoresce with different colors and brightness.

These mutant forms of GFP have facilitated the imaging of a variety of cellular processes and have revolutionized fluorescent microscopy. Since many fluorescent stains are toxic to cells or their components, the nontoxicity of GFP allows many cellular processes to be directly observed in living cells for the first time. While GFP mutants are being optimized in Tsien's laboratory to guide cancer surgery, more prosaic uses have now been commercialized, including glowing zebra fish for the aquarium trade and even the production of fluorescent pigs in Taiwan.

Disease Prevention

Seaweeds to Deworm Children

In southern Japan, children are traditionally treated for internal parasites with a red seaweed called "kainin-sou" (*Digenea simplex* (Ceramiales)). In 1953, an excitotoxic amino acid, kainic acid, was isolated from the alga. Laboratory animals dosed with kainic acid went into seizures. This observation led to the discovery of AMPA-kainate receptors on motor neurons. Currently, kainic acid is used to study Alzheimer's disease, epilepsy, and neurodegenerative illness. Recently, an unusual pattern of epilepsy among California sea lions was studied by Goldstein at the University of California, Davis. Intoxication of these marine mammals was traced to a structurally similar amino acid, domoic acid, produced by harmful algal blooms. Models of kainic acid activity were used to analyze excitotoxicity in the sea lions. Today, careful studies of AMPA-kainate receptors in motor neurons may lead to new cures for amyotrophic lateral sclerosis and other motor neuron diseases.

African Trees and Anti-Schistosomiasis Soap

Millions of people in Africa are deprived of healthy lives by schistosomiasis. Characterized by fever, enlargement of the liver, fatigue, and chronic diarrhea, schistosomiasis is a debilitating chronic illness caused by freshwater parasites that burrow into the skin and then travel to the liver. There they produce eggs which are expelled in feces. The parasites require snails to complete their life cycle. Although drugs such as praziquantel can treat schistosomiasis, such pharmaceuticals

are often unavailable to poor villagers. Even when entire villages are treated, reinfection from contaminated streams and rivers can quickly reoccur.

Control efforts for schistosomiasis depend on eliminating the snail host. At the University of Lausanne, Switzerland, Kurt Hostettmann has been studying saponins from African tree species that are toxic to schistosomiasis-carrying snails. The late Ethiopian physician Aklilu Lemma and Ethiopian horticulturalist Legesse Wolde-Yohannes received the Right Livelihood Award, considered an alternative Nobel Prize, for their studies of the vine *Phytolacca dodecandra* (Phytolaccaceae) as a means of controlling the snails. Known as "endod" or "African soapberry," these vines are used as fish poisons as well as soaps and shampoos. If crude extracts of such plants could be included in washing soap sold to villagers, the lives of millions of poor people could be dramatically improved.

Guam Cycads and Motor Neuron Disease

Soon after World War II, US Army physicians recorded an extremely high rate of a devastating paralytic illness among the Chamorro people of Guam. Now known as ALS/PDC (Amyotrophic Lateral Sclerosis/Parkinsonism Dementia Complex), this disease is believed to result from a traditional diet rich in the neurotoxic amino acid β -N-methylamino-L-alanine (BMAA). BMAA is found in the cycad seed flour used by the Chamorros as well as in animals they hunt which forage on the cycad seeds.

Symbiotic cyanobacteria in specialized roots of the cycad plants produce BMAA, and there is now concern that human beings outside of Guam may be exposed to BMAA from cyanobacterial blooms in lakes, estuaries, and marine systems as well as from cyanobacterial dust in desert areas. Double-blinded studies of Alzheimer's and ALS patients show BMAA present in their tissues, but not in healthy controls. Currently, new drugs are being designed to remove or block BMAA in the body as a possible treatment for ALS and Alzheimer's disease.

Environmental Remediation

Oil-Eating Bacteria

With the ongoing specter of oil spills from tankers, ocean-based drill rigs, and pipelines, the need for remediation strategies has never been greater. Enter *Alcanivorax borkumensis*, a small bacterium that thrives on petroleum. Able to feed on both hydrocarbons and alkanes abundant in oil, this bacterium occurs naturally near oil seeps in marine environments. Vitor Martins dos Santos, now at the University of Wageningen, sequenced the large genome of *A. borkumensis* in search for gene sequences that can be inserted into synthetic organisms designed to degrade oil spills.

Terry Hazen at Lawrence Berkeley Laboratories found that soon after the 2010 Deepwater Horizon oil spill in the Gulf of Mexico, populations of *A. borkumensis*, which are typically rare in the ocean, exploded. Hazen has continued to assay microbial diversity near deep-water seeps in order to expand the repertoire of possible organisms and genes that can be used to develop novel strategies for oil spill remediation.

Biodiesel from Algae

World energy consumption is growing while the availability of fossil fuels is diminishing. Efforts to produce corn-based ethanol and soybean-based biodiesel cannot meet all energy demands due to competing needs for prime agricultural land. Salt-tolerant algae can potentially meet this need as some species can grow in desert ponds using marginal water with high salinity. In the Great Salt Lake, Utah, the green alga *Dunaliella salina* (Dunaliellaceae) exists at high salinities – up to 27% – which may be significant in pointing the way for the biofuels industry to produce biodiesel using marginal water supplies. Development of *Dunaliella salina* as an alternative source for fuel will reduce the need for freshwater for bioreactor development while eliminating the possibility of contaminating freshwater supplies from bioreactor effluents. Today, one gallon of algal biodiesel sufficient to power an automobile, truck, or tractor, costs \$33. As a result, significant introduction of algal biofuel into the energy mix of the United States must wait until the cost of fossil fuels exceeds the production costs of algal biofuels.

Genetic Analysis

DNA Fingerprinting and Taq Polymerase

In 1993, Kary Mullis at Cetus Corporation shared the Nobel Prize for his discovery of the polymerase chain reaction (PCR) which, when combined with thermal cycling, allows rapid amplification of DNA from a single strand. The PCR technique is used in DNA fingerprinting for forensic purposes to amplify even trace amounts of DNA. The advent of PCR has resulted in the exoneration of scores of death row prisoners who were falsely convicted of capital crimes.

The first PCR techniques depended on a DNA polymerase extracted from the bacterium *Thermus aquaticus*. *T. aquaticus* was harvested from a thermal pond in the Lower Geyser Basin in Yellowstone near the Great Fountain Geyser. In 1969, Thomas Brock and Hudson Freeze provided a sample of this thermophilic bacterium to the American Type Culture Collection (ATCC). This bacterium thrives at 70 °C, a temperature which would split apart the double-stranded DNA of most organisms. Using a *T. aquaticus* sample from the ATCC, a public repository, in 1976, Alice Chien and colleagues at the University of Cincinnati isolated a new DNA polymerase from the bacterium.

Mullis and his colleagues at Cetus used Taq polymerase to develop the polymerase chain reaction. Since this DNA polymerase is heat resistant, it is possible to break apart DNA strands at low temperature and then reassemble them at a higher temperature. Because the molecule was derived from an organism originally collected from a US National Park, the profits derived by the patent owners have resulted in considerable controversy. Cetus eventually sold the Taq patents for \$330 million. While the National Park Service claims federal ownership of the original *T. aquaticus* specimen, it does not have legal rights to the subsequent research results. Yellowstone National Park now seeks to enter into benefit-sharing agreements with researchers prior to discovery of novel molecules.

DNA Fingerprinting and Pfu DNA Polymerase

One of the problems with Taq polymerase is that it has a relatively low replication fidelity, with an error rate of 1/9000

nucleotides. The discovery of Taq polymerase therefore led to a search for other DNA polymerases that have proofreading activities. Karl Stetter at the University of Regensburg, Germany, studied geothermally heated marine sediments on Vulcano Island, Italy, and discovered the archeal species *Pyrococcus furiosus*. This microorganism can withstand considerable fluctuations in temperature, and thrives at temperatures around 100°C. Studies by scientists at the US biotech company Stratagene resulted in the isolation of Pfu DNA polymerase, which has a replication error rate of only 1/1.3 million nucleotides. It has, unlike Taq polymerase, a 3'–5' exonuclease proofreading capability, and thus has now exceeded Taq polymerase in popularity for PCR cloning.

Novel Materials

Seagrass Insulation

From 1907 to 1960, farmers collected leaves of the seagrass *Zostera marina* from beaches in Nova Scotia. Sandy Wyllie-Echeverria at the University of Washington, USA, has analyzed the commercial gathering of seagrass leaves, and finds that at its peak in 1929, the seagrass industry of Nova Scotia sold 462,744 kg of leaves. These leaves were purchased by Samuel Cabot, Inc. to produce high-quality insulation for houses, hotels, hospitals, and lecture halls. By 1930, 350 apartment buildings in New York City and 200 commercial buildings were insulated with seagrass, including Carnegie Hall. The seagrass insulation proved to have extraordinary insulation and acoustic values and to be resistant to fire. However, the onset of World War II interrupted the seasonal gathering of seagrass, and the advent of fiberglass insulation resulted in the demise of the seagrass industry. Currently, there is industrial interest in basing a biomimetic acoustic insulation for concert halls and recording studios on the morphology of seagrass leaves.

Pharmaceuticals and Global Public Health

Malaria

Artemisia annua (Asteraceae) has been used in China to treat malarial fevers for 2000 years. This species is the source of the antimalarial drug artemisinin, known as *qinghaosu*. This compound is combined with other antimalarial drugs in artemisinin-based combination therapy (ACT.) One such ACT, Coartem, developed by the Swiss pharmaceutical company Novartis is used on multiple continents to assist with the battle to control malaria. An important advance has also been made in the creation of sweetened pediatric dispersible tablets for children, as the adult formulation of Coartem is bitter.

One of the major challenges in the creation, distribution, and utilization of ACT is the low yield of the compound from *Artemisia annua* plants. Although *A. annua* is a fast growing species, the global demand has caused the price and availability to hinder inexpensive versions of ACTs. One innovative solution to the challenge has been successful production via synthetic biology of artemisinin, pioneered by Jay Keasling of the University of California, Berkeley, USA. The large scale production of lower cost ACT combination therapies is being executed as a result of the fruits of biospecting, traditional

knowledge and state of the art scientific advances in synthetic biology.

Diarrhea

The current cornerstone of management of diarrhea and dehydration, oral rehydration solution (ORS), has no effect on the severity or duration of diarrhea. Crofelemer is an investigational drug being developed by Napo Pharmaceuticals in California for the treatment of secretory diarrhea from various causes. This antidiarrheal agent is an isolated and purified compound from the latex of the Amazonian tree species, *Croton lechleri* (Euphorbiaceae). Crofelemer is a partial antagonist of the cystic fibrosis transmembrane receptor (CFTR) chloride channel and has activity on the calcium activated chloride channel (CACC). This compound inhibits chloride ion secretion into intestinal lumen and the resulting gastrointestinal fluid accumulation. Based on its mechanism of action of blocking chloride ion secretion through CFTR and CACC, crofelemer has been investigated as an agent for the treatment of secretory diarrhea in patients with *Vibrio cholera* induced diarrhea, traveler's and infectious diarrhea, HIV-associated diarrhea, and irritable bowel syndrome.

To make crofelemer universally accessible within low income countries, following the drug's regulatory approval, the *Crofelemer Access Program* (CAP) by Napo Pharmaceuticals will make a pediatric formulation of crofelemer available at cost to collaborating multilateral, nongovernmental and nonprofit organizations such as Direct Relief International.

HIV

Current state of care for patients with HIV/AIDS is highly active antiretroviral therapy (HAART) which consists of a cocktail of drugs, including reverse transcriptase inhibitors and CD4-site blockers. While effective in extending the life expectancy of HIV/AIDS patients, HAART has some negative side effects. In addition, it is costly, particularly for people in developing countries, and does not eliminate the virus from the body; for example, if medication ceases, a high viral titer quickly returns. One promising drug on the horizon is Prostratin, isolated from a plant, *Homalanthus nutans* (Euphorbiaceae), the bark of which is used by Samoan healers to treat hepatitis. As a phorbol, Prostratin is unusual in that it activates protein kinase C but is not a tumor promoter. Prostratin is able to clear laboratory animals of virus.

The product of an ethnobotanical research program of Paul Cox, now at the Institute for Ethnomedicine, and investigators at the National Cancer Institute (NCI), Prostratin is being developed by the AIDS Research Alliance (ARA) in California. Negotiations between the healers, village chiefs, and the Government of Samoa resulted in a landmark benefit-sharing agreement which guarantees stakeholders in Samoa 20% of ARAs profits. A second agreement with Jay Keasling and the University of California, Berkeley resulted in a 50% share of profits from the gene sequence for Prostratin being returned to Samoa.

Pain and Addiction

The roots of iboga (*Tabernanthe iboga* (Apocynaceae)) are used throughout central Africa to induce a hallucinogenic experience that serves as a rite of passage into adulthood and which

also can treat female sterility. These hallucinations are claimed to render insight as to the causes of sterility, and to facilitate contact with a villager's ancestors. The indole alkaloid ibogaine as well as its metabolite noribogaine are now under investigation by Deborah Mash at the University of Miami Brain Bank for treatment of chronic pain and to help deal with addiction. Initial clinical trials in St. Kitts with heroin addicts have been highly successful (Mash *et al.*, 2000). The Miami biotech firm DEMERx is seeking FDA approval for an ibogaine treatment for chronic pain.

Cancer

Bioprospecting has yielded multiple drugs approved by the FDA to treat various forms of cancer including vincristine and vinblastine isolated from the Madagascar periwinkle *Catharanthus roseus* (Apocynaceae). Vincristine and vinblastine are drugs of choice for the treatment of pediatric leukemia. Taxol, a drug marketed by Bristol-Meyers Squibb, is used to treat ovarian and breast cancer. Taxol was isolated from the Pacific yew tree *Taxus brevifolia* (Taxaceae) during a systematic search by the National Cancer Institute. Currently, Lars Bohlin at Uppsala University and Samantha Gerlach at Tulane University are studying cyclotides, small cyclic peptides from the Violaceae and Rubiaceae, as a new category of biodiversity derived anticancer compounds.

Some innovative research programs are analyzing complex mixtures of plant and other naturally occurring substances used in traditional Chinese medicine and Ayurvedic medicine from India for new anticancer treatments. New Earth Biomed (NEBM), a not-for-profit cancer research organization, is currently evaluating such alternative treatments.

Intellectual Property

Patents and Natural Products

Patents and Exclusionary Rights

A patent is the right granted to an inventor by a government to exclude others for a limited time from selling an invention in the marketplace. As government grants, patents are only enforceable within a limited jurisdiction; for example, US patents are enforceable only within the US, Japanese patents are enforceable only within Japan, etc. Thus a US patent cannot prevent any individual or firm from producing or marketing a pharmaceutical in Costa Rica, China, or Indonesia. Instead, patents would have to be granted by each of these countries to exclude unauthorized sellers. As a result, most pharmaceutical patents are filed only in large industrialized countries where significant revenues are anticipated. Patents do not, therefore, typically exclude traditional non-commercial uses, or uses in biodiverse developing countries. Once a patent expires, anyone can make or sell the invention without restriction. Patent law has been developed to encourage research and innovation by allowing inventors, for a time, to enjoy the financial proceeds of their invention, before the invention becomes public property.

Patents are particularly important in the development of new drugs, since few pharmaceutical firms would risk the \$700–850 million in research and development costs needed

to bring a new drug to the market if they did not have a reasonable expectation of recouping these costs via patent protection. In the absence of patents, pharmaceutical development and the creation of new drugs would largely cease.

Patentability of Natural Products

There is an incorrect perception that naturally occurring molecules cannot be the subject of patents. If a new chemical structure is isolated from a species found in nature, and it has not been described in the scientific literature, a patent can be applied for a new "composition of matter" patent. If that novel composition of matter has a use or utility, that is not obvious, a patent may be granted by a patent office, depending on the scientific data presented and the rules of a specific country's patent office. If a naturally occurring compound that has previously been described in the literature, i.e., it is already in the public domain, but there is a novel, as yet never described use for that compound, an inventor may apply for a use patent. The novel use for this compound however must not be obvious or previously described in the scientific literature.

Myriad Genetics and Bioprospecting Patents

Patent law prohibits protection for inventions that are obvious, such as sunlight or pollination, or that do not involve significant innovation on the part of the inventor. As a result, pharmaceuticals based on biological diversity can face special challenges under patent law.

Myriad Genetics, a Utah-based biotech firm, recently lost a major court case to defend their patent on the use of human BRCA1 and BRCA2 genes for predicting risk of breast cancer in women. The Myriad testing procedure currently costs about \$3000 per patient, so the Association for Molecular Pathology and the American Civil Liberties Union sought to overturn Myriad's US patent. They argued that patenting human genes is in violation of § 101 of 35 US Code. The initial court ruling, which was against Myriad Genetics, stated that "purification of a product of nature (in this case, DNA from patients), without more, cannot transform the product into patentable subject matter." Because Myriad failed to prove that there were "markedly different characteristics" between natural BRCA1 and BRCA2 genes and the isolated DNA from test subjects, the court awarded summary judgment against Myriad.

Renowned patent attorney John Wetherell notes that this case appears to echo a 1948 ruling in *Funk Bros. Seed v. Kalo Inoculant*. In this case Funk Bros. Seed company obtained a patent for a natural *Rhizobium* inoculant. In *Funk Bros. Seed v. Kalo Inoculant*, the court overturned the patent because the bacterial mixture was held to be "obvious."

If the case against Myriad Genetics is upheld on appeal, there is concern that many current biodiversity-based patents could be at risk, including those for naturally occurring compounds such as DNA polymerases, enzymes, antibodies, microbes, cell lines, stem cells, and gene replacement therapies. Any patents from natural products that are not naturally occurring or which have a different use from their use in nature, such as mutant DNA or drugs from nonhuman sources, such as Taxol, will probably remain valid. Given the massive investment required to bring new biodiversity-based products

to market, loss of the Myriad Genetics' appeal will likely be the death knell of the nascent bioprospecting industry.

Patents and Traditional Knowledge Systems

Ayahuasca – the Vine of the Soul

International debates continue on the ethics of patents, drug development, public health, and human rights. Many private and public biotech and pharmaceutical firms rely on investors who are seeking a return on their investment. One of the primary ways that companies protect their large capital investments in research and development is through filing, prosecution and maintenance of patents. This has become a controversial topic in the international development, human rights, environmental and indigenous rights community. The controversy is based in part on the historical lack of appropriate access and benefit-sharing (ABS) with the people, cultures, and countries that have been the origin of multiple new therapeutic agents.

The controversy revolves around traditional knowledge, particularly historic uses of plants. In 1986, Loren Miller, a California entrepreneur, obtained US plant patent 5751 for a cultivar of ayahuasca, *Banisteriopsis caapii* (Malpighiaceae), a hallucinogenic plant used ritually in South America. He termed his cultivar "Da Vine," and claimed he collected it growing in a domestic garden in the Amazon. When indigenous tribes in the Amazon learned of the patent, they protested. In this they were supported by CIEL (the Center for International Environmental Law) in Washington, DC. Representing the tribes, CIEL argued in 1991 that the patent on the "Da Vine" cultivar should be rejected because it was not new, the plant was obtained in an uncultivated state, and that issuing a patent on a plant that is sacred to indigenous people "violated notions of public policy and morality." On May 28, 1999, the US Patent and Trade Office (PTO) rejected Miller's patent on the narrow grounds that the cultivar was indistinguishable from herbarium specimens at the Field Museum made prior to the filing date of the patent. However, Miller appealed the ruling. On April 17, 2001 the PTO affirmed that both the cultivar "and its medicinal properties" were patentable and reinstated the patent for the remaining two years of the patent life. The plant patent protected only Miller's original specimen and plants produced from its cuttings.

Fortunately national patent offices are being provided links to existing databases on the traditional use of biodiversity so that there are fewer inappropriate cultivar patents issued. In addition, detailed national databases on the traditional knowledge and use of plants are being created by governments in areas with a rich and ancient history of traditional use of plants, such as India and China.

Patent Limits and Costs

In general patents are valid for 17–20 years. Companies sometimes attempt to file additional patents to extend the time line of the patent estate, a process often referred to as "evergreening a patent position" but those efforts are not always successful. Many indigenous cultures object on ethical grounds to patenting any compounds, plants, or processes that are linked in any way to their traditional knowledge and

cultures, especially if there is no prior informed consent or benefit sharing linked to the patented material. It is important to note as well that many indigenous cultures focus on the well being of their people, communities, and ecosystems on timelines of 500 years or more. Once a patent has expired after 20 years it is forever in the public domain and can be used freely by anyone. In that sense a 20-year period of time seems to be a short time span when compared to the larger time horizon of indigenous communities.

Patent Pools

Application and maintenance of a patent or several related patents often costs several hundred thousand dollars in legal and government fees over a period of many years. The ownership of a patent in and of itself does not bestow or have an actual value unless it protects a product or process that has some commercial utility. This means that many companies, large or small, nonprofits or individuals may expend large sums of money to obtain patents that never have any use or value. In patents related to bioprospecting, few products actually are ever developed or commercialized. There is an incorrect perception that once a patent is issued that there will be a rapid return of financial benefit, which is usually not the case.

Fortunately there is a movement among many for profit and nonprofit companies to make existing patents on natural and synthetic products available in "patent pools" for free access in order to facilitate the development of drugs and vaccines for neglected diseases. Many universities, nonprofit research foundations and companies are utilizing these patent pool resources to accelerate the development of therapeutics for diseases such as malaria, TB, chagas disease, cholera, and many other debilitating infectious diseases.

Bioprospecting and Ethics

International Agreements

The Convention on Biodiversity

The sustainable development of genetic resources and equitable sharing of benefits are core principles of the Convention on Biological Diversity (CBD) that was ratified in 1993 by most countries of the world. The purpose of the CBD was to incentivize biological conservation by encouraging partnerships between biodiversity-rich nations and technologically rich countries. The major challenges related to sustainable development and bioprospecting revolve around the implementation of these core principles at the national and international level.

Use of Indigenous Knowledge under the Convention on Biodiversity

Article 8(j) of the Convention on Biodiversity obligates the parties to preserve indigenous knowledge, find broader applications for its use, and to ensure that the benefits of the knowledge are equitably shared with the traditional custodians of that knowledge. Yet the rights and benefits that should be accorded to indigenous and local communities when scientists, whether academic or corporate based,

conduct research in foreign nations has become a contentious topic (Brown 2004).

One of the unintended consequences of the CBD was a more complicated and slow process for taxonomists, ecologists, and other biologists to obtain permits to conduct basic research in biodiversity-rich nations. In many countries it is far easier to obtain permits to clear cut entire forests than to collect a 50 mg sample of a plant for study. Some individuals in biodiversity-rich countries feared that all scientific researchers were essentially agents of bioprospecting organizations seeking to plunder and exploit their natural resources. This was largely a false obsession. Individual scientists, companies, or government consortia such as Shaman Pharmaceuticals, Diversa, the National Cancer Institute and the International Cooperative Biodiversity Groups (ICBGs) sought even prior to the CBD to establish ethical research and benefit-sharing relationships.

An Example of Pre-CBD Benefit-Sharing Agreements: Prostratin

As previously described, Prostratin is being developed by the AIDS Research Alliance as a possible treatment for HIV/AIDS. Originally discovered in the 1970s in species of *Pimelia* (Thymelaceae) which had proved toxic to livestock in New Zealand and Australia, Prostratin was again isolated in the mid-1980s from *Homalanthus nutans* in Samoa. The stem bark of *H. nutans* was recorded by ethnobotanist Paul Cox (then at Brigham Young University (BYU)) to be used by two separate healers to treat hepatitis. After first negotiating benefit-sharing agreements with the healers, the village chiefs, and the government of Samoa, Cox provided samples of *H. nutans* to the National Cancer Institute (NCI) to run against an *in vitro* test for HIV/AIDS. These negotiated agreements were formalized in 1989 (four years before the CBD) as "The Falealupo Covenant." With permission of the village chiefs and the Samoan Prime Minister, a use patent for Prostratin as an antiviral compound was filed by the NCI and BYU with the proviso that any commercial developer of Prostratin would first be required to negotiate a fair and equitable return with the Samoan people before obtaining a license from NCI. Publication of this requirement in the *Federal Register* by NCI resulted in benefit-sharing agreements negotiated between the AIDS Research Alliance and Samoa in 2001 and the subsequent agreements between UC Berkeley and Samoa in 2004, all of which were signed by the village chiefs and the Prime Minister of Samoa, after review by the Samoan Attorney General. In accord with the agreements, water tanks, a small medical clinic, a trail system, three schools, and an aerial rain forest walkway, with aggregate value exceeding \$500,000, were constructed in the village (Cox, 2001). All of the tourist revenues from the walkway are retained by the village. Cox was honored with a chiefly title, Nafanua, by the villagers. His efforts to conserve the Falealupo rain forest were recognized by a Goldman Environmental Prize shared by Cox and village chief Fuiono Senio in 1997.

In 2009, Cox was attacked in the Samoan press by a US NGO (nongovernmental organization), M-Cam, who claimed that the Prostratin use patent was illegal since the Samoan healers were not listed as co-inventors. M-Cam also argued that the benefit-sharing agreements signed by the villagers and

the Prime Minister were of no value. Although the NGO claimed to represent the healers, neither healer families nor the village chiefs said they were familiar with the NGO, which persisted in misspelling the healer's name in their press releases. Finally, in 2010 the village chiefs issued an extraordinary declaration in both Samoan and English, which was published in the national newspaper and signed by 87 village chiefs. In this statement, the chiefs reaffirmed the validity of the original benefit-sharing agreements, declared that Cox held a chiefly title and enjoyed their trust, and asked that outsiders cease from interfering with what they considered to be village matters.

Bioparasites and Indigenous Knowledge

Implementation of the principles of article 8(j) of the CBD when working with indigenous communities and local communities is not always easy – not because local communities do not want to partner with researchers in ways that can benefit their communities and families – but because of the emergence of a new form of NGO, termed by some as “bioparasites.” Bioparasitic NGOs, supported by funds from foundations, governments, and the private sector ostensibly seek to protect indigenous peoples and local communities from exploitation by scientists, who they claim will continue the cycle of colonial exploitation of the last century. The irony is that these NGOs seeking to represent the interests of indigenous communities often function in a paternalistic and colonial manner, the presumption being that indigenous peoples cannot make their own choices and decisions, nor negotiate effective relationships with outside researchers. However, in Latin America, Africa, Southeast Asia, and the South Pacific, there are strong examples of indigenous communities that know what they want and are effective at negotiating, communicating, and managing partnerships with biodiversity researchers. Some bioparasitic NGOs have urged countries to totally close their doors to scientific research. In countries with rapid loss of biodiversity due to logging, mining, and agricultural expansion such closure would in essence guarantee that their biodiversity will be lost before it is ever screened for useful compounds.

Problems became more pronounced when the bioparasites began to siphon sufficient resources to travel all over the world “on behalf of and representing” indigenous and local communities at meetings focusing on access and benefit sharing. When queried, many of the bioparasitic NGOs are unable to speak the local language, are unacquainted with the local customs, and are unable to name or even spell the name of a single villager.

Concomitant with the rise of bioparasitic NGOs, the actual indigenous community leaders were, at least in the first 10 years after the ratification of the CBD, often not included at important international forums on ABS. To complicate matters further, many national governments did not accord the indigenous and local communities a legal voice or stake in the sharing of what was deemed under the CBD as sovereign national resources.

Ethnobiologists, with long standing relationships and respect for indigenous and local communities, have become new targets for bioparasitic NGOs. As a result several very sound and long standing effective relationships and programs,

such as the ICBG program of the highly respected husband and wife team of Brent and Elois Ann Berlin were terminated by the US Government, due to a successful bioparasite effort that divided indigenous communities in Southern Mexico.

Effective Indigenous Negotiators

Bioparasitic NGOs do not always prevail, however. For example, the indigenous Ingano people, in an effort to produce a sustainable harvest and management program for *Croton lechleri* latex with tangible benefits for their communities, successfully negotiated (with local government approval) with the Colombian FARC. These negotiations with a militarized group represented an extraordinarily sophisticated ability on the part of the Ingano people to effectively pursue community benefits despite significant risk. In this case the bioparasitic NGOs did not interfere, possibly due to the strength of the indigenous communities own management of their choices, fear of the FARC or out of appropriate respect for the decision making process of the Ingano people.

The 2010 COP(10) Meeting in Nagoya

In October 2010, an important milestone was achieved at the 10th meeting of the conference of the parties (COP(10)) of the Convention on Biological Diversity, in Nagoya, Japan. During this meeting an agreement on ABS, called the “Nagoya Protocol on Access and Benefit Sharing” was approved, along with several other measures to help halt the loss of global biodiversity. The Nagoya ABS protocol provides greater details and specific requirements on benefit sharing and access agreements. Likewise, indigenous groups have sought stronger national and international recognition of their rights to resources on their ancestral lands and to their traditional knowledge. Hopefully, the new ABS protocol will facilitate achievement of these goals. Scientists will now have a simpler process to gain access for academic research as national governments streamline the permit process as part of the Nagoya ABS protocol. Each country is required to have a focal point for the process of requesting biodiversity access permits. The requirements for prior informed consent and the establishment of benefit-sharing agreements have been reinforced.

There was a desire by some parties to have the Nagoya protocol become retroactive but that was not approved. Instead as a compromise there was a call for a “Global multi-lateral benefit-sharing mechanism” to address genetic resources that were acquired prior to the new agreement.

Data Return and Public Health

One of the other ways bioprospecting can enhance local communities is through data return programs when scientists send back data on the results of their research. Providing data on the safety and efficacy of plant medicines to integrated clinics and rural health programs, can enhance traditional medicine, which is especially important in areas with limited access to “western medicine.” In one example described by Scheinman (2000) in Tanzania, data provided by Shaman Pharmaceuticals helped the Tanga Aids Working Group expand the use of a plant that was demonstrated to have *in vitro* efficacy for herpes. In this case, traditional healers and western trained medical doctors collaborated in the treatment and management of people living with HIV/AIDS within and

outside the hospital setting. Shaman Pharmaceuticals also returned data on the *in vivo* activity of plants used to manage type 2 diabetes to healers and collaborating research groups in Asia, Africa, and Latin America (Richter and Carlson, 1998).

Books, manuals, and school materials on plant medicine have also been generated and returned to collaborating healers, clinics, and research groups in Belize and Micronesia by Michael Balick at the New York Botanical Garden, while Cox has provided copies of Manandhar's *Plants and People of Nepal* to every school and community library in Nepal. Studies of traditional medicine and health care practices can provide long-term documentation on the botanical, cultural, and medical uses that can be integrated in rural and urban health care and conservation programs (Lee *et al.*, 2010; Balick and Arvigio, 1998).

Benefit Sharing in Practice

There are examples of benefits sharing programs that have been practiced for several decades, in some cases, as part of collaborative research and development activities with communities, indigenous peoples and governments.

Shaman Pharmaceuticals

In the early 1990s, Shaman Pharmaceuticals sought to develop new drugs through ethnobotanical research collaborations with indigenous communities in 25 countries in Latin America, Africa, and South East Asia. Early in the formation of this company, a mechanism for the return of benefits was established: a nonprofit organization named the "Healing Forest Conservancy" (HFC) (King, 1994). The collaborating communities agreed that benefits from any drug that might be developed should be shared equally among the collaborating cultural groups, as it would be impossible to predict in advance where a successful drug lead might come from. It was also agreed that the time line for benefit sharing in the drug development process, at times 10–15 years or longer, was unacceptable to indigenous communities. Providing immediate and medium term reciprocity was therefore incorporated into the benefit-sharing process, in addition to the long-term benefits resulting from drug discovery (King *et al.*, 1996).

The company committed 10–15% of each field research budget to fulfill benefits as determined by the local community. Examples included clean water systems/piping for groups in Ecuador and Indonesian Borneo, beds and mosquito nets for a maternity clinic in Tanzania, a boat and engine for emergency medical evacuations for healers in the Sese, Islands of Uganda in Lake Victoria, funds for land demarcation for the Matsigenka people in Peru, visits of dentists to a remote Quichua village in Ecuador, the extension of a dirt airstrip in the same village to facilitate visits of dentists and emergency evacuations of critically ill people, and support for an Ingano medicinal plant community garden in Colombia (Moran *et al.*, 2001).

The HFC also conducted workshops with local people, supported conservation projects and executed a pilot return of resources to test the long-term benefit-sharing process in Nigeria. The pilot benefit-sharing process was published as a

case study by the Secretariat of the Convention on Biological Diversity (Moran, 1998). Shaman Pharmaceuticals did not succeed but the research programs and lead clinical drug assets, such as the antidiarrheal compounds previously described, were purchased by Napo Pharmaceutical Inc. in 2001. The long-term benefit-sharing commitment of the Healing Forest Conservancy and Shaman Pharmaceuticals was formally adopted by the board and management of Napo Pharmaceuticals and that drug is in the final stages of development and commercialization in 2011.

Conservation, Sustainable Development, Fair Trade, and the Management of Products Derived from Biological Diversity and Traditional Knowledge

Hundreds of consumer products worldwide have been developed and marketed that were derived from traditional knowledge. There is a need to ensure that the harvesting and cultivation of these products is conducted in a manner that is sustainable and provides fair trade income for individuals, families, communities, and cooperatives. There are now multiple international organizations that evaluate and certify such practices so consumers can elect to utilize products with maximum benefit to ecosystems and communities.

These general principles are evolving to be the guiding structure of ethical trade and are articulated in the Biotrade Initiative of the United Nations Conference on Trade and Development (UNCTAD):

- To work to conserve biological and cultural diversity
- To maximize the sustainable use of biological diversity
- To facilitate the fair and equitable sharing of benefits from the use of biological diversity
- To focus on socio-economic sustainability, product, financial, and market management
- To comply with national and international regulations
- To conduct all work with respect for the rights of all stakeholders involved in the sustainable management
- To respect land tenure, use and access to natural resources and knowledge

Companies are asked to reaffirm their commitment to the following objectives:

- To create social and environmentally responsible management systems
- To support long-term ecosystem conservation
- To maximize wildlife protection and water conservation
- To provide fair treatment and good working conditions for all, with a focus on the occupational health and safety of local communities
- To focus on long-term community relations
- To create, manage and maintain integrated plant and animal production systems
- To enhance and improve soil management and conservation of microbial diversity
- To focus on maximizing the sequestration of carbon by utilizing whatever methods available to capture and retain CO₂ as part of the sustainable management and harvesting of any and all commercially traded plant or animal species.

Companies engaged in marketing products that are wild harvested are also encouraged to meet Fair Wild Standards:

- To maintain wild plant resources
- To prevent negative environmental impacts
- To comply with laws, regulations and agreements associated with wild harvesting
- To respect customary rights
- To engage and promote fair contractual relationships between collectors and the companies
- To limit participation of children in wild collection activities
- To help facilitate benefits for collectors and their communities
- To apply, develop and continually evaluate environmentally responsible ecosystem management practices
- To apply socially responsible business practices and promote buyer commitment.

Intellectual Credit for Discoveries Based on Traditional Knowledge

There is a consistent message from healers, village leaders, and other indigenous peoples. They ask that they be accorded the proper intellectual credit for their traditional knowledge. Unfortunately, most pharmacy or medical textbooks do not provide credit to traditional knowledge as the origin of many important medicines. High school and lower grade books also do not identify the tremendous contributions that traditional knowledge has provided to the western pharmacopoeia. Such recognition can also enhance the integration of traditional medical systems with national public health programs, since the World Health Organization estimates that 80% of the world's populations rely on traditional health care practices.

Bioprospecting and the Sacred

Indigenous leaders and ethnobiologists, such as Maui Solomon, have expressed a deep concern about the codification of traditional knowledge. One of their primary concerns is that the profound spiritual linkage of traditional peoples to the earth and their indigenous cosmologies are being unduly commoditized. For example, in Australia, indigenous communities have protested the appropriation of their iconic symbols for the manufacture of trendy clothing and handbags; they have sought in a type of trademark protection to prevent profaning their sacred symbols. Similar concerns are arising among Native American communities in the American southwest, where petroglyphic symbols considered by some to be sacred, such as Kokopelli, now adorn beer can holders. Recognition of the sacred among indigenous cultures by researchers from an increasingly secularized west is one of the most profound issues facing biodiversity research. Although there is tremendous diversity among indigenous cultures, all appear to agree that the earth and its biodiversity are sacred. Individuals involved in bioprospecting programs should show proper respect for the spiritual values of traditional peoples. What is required is a sincere respect for the cultures, people, and spiritual values embodied in traditional knowledge and ecosystems. As articulated by noted botanist and conservationist Peter Raven "we need to show love, compassion and respect for all creatures on this planet."

Glossary

Aggregation Combining several potentially separate components of a system to simplify analysis.

Dynamic model Mathematical description of a system with components that vary in time.

Model A construct, physical, mathematical, or computational, that is a simplification of reality developed to meet certain objectives.

Multimodel Single integrated model that links together models utilizing different mathematical or computational approaches.

Parameter Constant in a model that must be estimated from data, or assumed to be of a particular value.

What Is a Model?

Just as storytellers can take their audience on trips to faraway places and provide a glimpse of life in different cultures, scientists tell their stories about the way the world works by making models. Such models never provide a complete view of how the world works, but do give us glimpses that help us to piece together interactions between different parts of the world and the processes that connect them. These models take many forms, some being mostly verbal, others mostly qualitative and graphical, some phrased in various mathematical forms, and still others set up as collections of rules within a computer program.

Models provide maps of varying levels of complexity to help us understand the topography of science. There are coarse road maps that provide merely the outline of major arteries for traffic, telling us nothing about buildings or other features of the landscape, but providing an overview of the linkages between key components of a system. More elaborate models show us the buildings and the infrastructure that links these buildings – the sewer and power lines. Even more complex models would indicate the humans in each building, their occupations, and the flow of money or capital goods between them. Similarly, models at many levels of complexity can be useful for addressing different questions in the study of biodiversity. A very coarse model might analyze the effect of land use change worldwide on total species richness. A more complex model could consider particular regions and analyze differentially the changes in land use within them and the associated changes in species richness. A still more complex model could consider the local dynamics of a population of a particular species and from this elaborate the dynamics of the population's abundance as well as the abundances of populations of other interacting species. A further level of complexity in model formulation would incorporate the feedbacks of land use on climate change, connect this to socioeconomic models that account for ecosystem services, and project how these forces impact biodiversity from local to global scales.

The Purposes of Modeling

General Objectives of Models

Which type of model one constructs depends on the questions being asked and the availability of data to construct a

reasonable model. Though there are many specific purposes for constructing models (Haefner, 2005), these may be grouped into a few general objectives: description, mechanism, prediction, and control. These objectives are not mutually exclusive, so that descriptive and mechanistic approaches may be used to aid prediction and control.

Description

Sometimes all that might be desired is a simple description of a collection of data. For example, an arithmetic or geometric average provides a single value to summarize a list of numerical data. The single descriptor used may depend on the type of data – for example, a geometric mean is typically more appropriate as a metric for summarizing varying growth rates than an arithmetic mean. A single descriptor may be sufficient for some purposes that do not require knowledge of how much variation is in the data. To assess variation, a dispersion measure such as variance would be needed. These summary statistics are coarse, ignoring many of the details in the data. Yet they do allow us to easily comprehend major differences between different data sets.

Extensive species lists within certain taxa from two locations may be compared by considering just the total numbers of species in the two locations and the number of species in common between them. Such a summary may be sufficient for a comparison of the two locations, while ignoring details such as the diversity within the taxa included. Descriptive approaches may be much more complex than simply providing averages and variances. Options for analysis of ecological data have grown tremendously due to the ready availability of computational platforms and open-source tools such as R. Bayesian methods and exploratory statistics approaches are applied to analyze complex multidimensional data (Whitlock and Schluter, 2008). Spatiotemporal analysis as an outgrowth of traditional time-series approaches is now feasible. In these the histories of species richness or abundances might be compared between locations or correlated with the histories of anthropogenic actions in the locations. Geographic Information Systems provide the functionality to analyze biodiversity across multiple regions, accounting for landscape metrics such as distance and connectedness.

Mechanism

If the objective is to provide an understanding of how a particular system operates, then it is necessary to take account of the processes that govern the system. While all such mechanistic models are descriptive at some level, the point is to deal with the basic physical, chemical, and biological processes operating in the system. This requires including those processes that operate at a spatial and temporal extent appropriate for the problem one is addressing, and ignoring others. Thus, analysis of how alternative global warming predictions would affect worldwide biodiversity might include the geographic variation in the temperature predictions at a spatial extent of hundreds of square kilometers, but would no doubt ignore the microclimate variation of every square meter. Even if it were possible to characterize the meter-by-meter temperature differences predicted to occur according to alternative warming trends, the lack of available detail on the species present at this detailed spatial resolution limits the utility of including such detail. Despite the lack of data at fine spatial resolution, it is feasible to consider hybrid methods that incorporate mechanistic biophysical models for constraints on species' presence linked to either statistical models based on climate data or down-scaled climate models. (Buckley *et al.*, 2010). A discussion of scaling issues is included elsewhere in these volumes.

Prediction

Predictive models are of two general types: those that attempt to project the behavior of the system based on certain explicit assumptions, and those that attempt to forecast the future behavior. The difference is between what might be true in the future if certain assumptions hold (projection) and what will be true in the future (forecasting; Caswell, 2001). In many biological situations, the forecasting problem is not even attempted, as it would involve taking account of a wide variety of unpredictable abiotic phenomena (e.g., hurricanes and droughts). It is often feasible to construct a model to project over some time period the future dynamics of a system based on current observations and particular reasonable assumptions about the interactions in the system. The majority of population models (discussed elsewhere in these volumes) are of this form, in which abiotic influences are not included. These models can project the future behavior of the population based on the biotic forces of demographics, genetics, and social structure within the population. Similarly, species distribution or niche models can project shifts in spatial patterns of species' presence based on assumptions on spatial climatic patterns. Uncertainties associated with unpredictable phenomena can be taken into account by attempting to project just the mean and variance of the variables of interest (e.g., population size), or by developing a stochastic model that incorporates assumptions about the probabilities of alternative future conditions. In the latter situation, projections would typically arise from numerous alternative simulations accounting for the assumed probabilities of different conditions, and the projections are therefore not single values or single spatial maps, but rather probability distributions for the values of interest.

Control

When a system has one or several components that are under human control, either completely or in part, then a model can be used to help determine how to apply such a control to meet certain objectives. Examples of controls are harvest quotas, limits on fertilization or pesticide application, flows from a dam, limiting importation of potentially harmful invasive species, and land use zoning regulations. Examples of objectives are maximizing biodiversity, minimizing population extinction probability, reducing the spread of nonnative species, and maintaining population size above some determined threshold (such as a minimum viable population size). Control models mostly focus on the dynamics of the system, with the simplest form of control being bang/bang, meaning on/off, such as allowing harvest in certain years and not allowing harvest in other years. A related objective is for control models to produce a relative comparison of alternatives in order to rank these alternatives according to some criteria (DeAngelis *et al.*, 1998). Still other control models are used to analyze the physiological responses of individual organisms to varying environments and the homeostasis that can arise through these responses. Spatial control involves choosing what action to carry out, where to do it, and when to apply the action. Many problems in spatial management of natural systems can be phrased as optimization problems in which the actions taken at different locations are constrained, often due to some overall budget limitations, with an objective to maximize some characteristic of the entire landscape, such as a diversity metric (Hof and Bevers, 2002).

Types of Models

Models can be physical, such as animal models used in drug testing and airplane models used in wind tunnels. In biodiversity contexts, microcosms and mesocosms, which are limited biological systems built in a laboratory setting, play this role. These are meant to mimic the key biotic forces interacting within a natural system, but are constructed at a spatial extent that allows for easy observation and controlled experimentation. They cannot include all of the components of the real system, but do allow for projection of how the real system might respond under particular perturbations. A wide array of model systems have been proposed as appropriate to evaluate responses of organism behavior and species interactions. Physical models are clearly limited, particularly to organisms that are mostly sessile or have very short distance movements.

Mathematical models come in a wide variety of forms. Some are simply graphical relations that show the qualitative relationship between certain components of a system, mainly to demonstrate the shape of response and whether one component increases or decreases with another. An example would be the increase and then decrease in species diversity along a gradient from low to high frequency of disturbance (Figure 1). Here, there is no attempt to predict at exactly what disturbance frequency the exact peak in species diversity occurs. Rather, the objective is to illustrate the qualitative behavior of diversity, representing the "intermediate disturbance hypothesis," which

Figure 1 Illustration of the intermediate disturbance hypothesis.

posits that high diversity occurs at intermediate disturbance frequencies.

The majority of mathematical models in ecology deal with the dynamics of populations and communities. Such models consider the basic processes of birth and death, immigration and emigration, and competition and predation to elucidate general theories of population dynamics. Described using differential or difference equations, these models allow for projection of the long-term behavior of populations, and provide methods to project the within-population structure (age, size, genetic, etc.) over time and space. These models can be expanded in numerous ways to incorporate between-species interactions, account for demographics of births and deaths, use discrete spatial units (e.g., islands or patches) as well as continuous spatial spread, and deal with the stochastic aspects arising particularly in small populations (Murray, 2007).

Computational approaches have become a standard tool in every area of ecology. Computers are used to analyze complex data, interpret the implications of mathematical models by carrying out numerical schemes to solve the mathematical models, and to create models that are not readily described through any other means than through computer code. A computer system is made up of the various components of a computer, including the central processing units, graphics processing unit, monitor, hard drive, and input/output devices, as well as software and peripheral devices such as external storage, along with network connections to other computers and external data sources. Computer systems designed for ecological monitoring and real-time analysis, as are being constructed for the National Ecological Observatory Network (www.neoninc.org), also incorporate specially designed workflow to visualize, manage, and analyze a variety of incoming data streams, and provide remote access to diverse users. Cyberinfrastructure projects, such as the iPlant Collaborative (www.iplantcollaborative.org), develop the computer systems and associated products and tools necessary to link information at various scales of investigation, from the genome to the whole organism, to the ecosystem. This article emphasizes the use of computers to model biological

processes, with the realization that technology affects our capacity to develop and investigate natural systems. The expectation is that our ability to mine large data sets arising from field-based and remote sensors, construct computational models from this, and evaluate the utility of these models will continue to expand. The advent of parallel computation, in which computational tasks are split among numerous processors, has greatly expanded the speed of computation, the range of problems we can address, and the methods we can use to address them. The flourishing use of Markov Chain Monte Carlo methods to carry out complex Bayesian modeling is one example of the continuing potential for advances in computational power to affect the science of biodiversity.

Computer models are quite varied in structure. All the standard mathematical models of populations and communities, constructed using differential or difference equations, may be implemented on computers. Indeed, since it may be quite difficult to develop analytical solutions for such models, analysis of their behavior often requires the use of numerical solution methods implemented on a computer. There are many computer models that, although they may have a description that is essentially mathematical in form, are really described by the computer code itself rather than an explicit set of mathematical equations. An example would be cellular automata models, one type of which consists of a two-dimensional lattice, with each point on the lattice having one of a number of states. The simplest situation would be each lattice point being occupied (e.g., in the 1-state) or unoccupied (in the 0-state). The model is then described by a set of rules that determines how the state of a lattice point changes from one time step to another, based on the states of surrounding lattice points. Such a cellular automaton may be used to mimic the spatial dynamics of populations, in which each lattice point represents a possible location of an individual. Alternatively, each lattice point can be interpreted as a local population, and the entire lattice can then follow the collection of such populations, called the metapopulation. It has been argued that the major questions in science are feasible to be investigated using cellular automata (Wolfram, 2002).

System simulation models are more elaborate computer models that attempt to include most of the major biotic and abiotic factors that affect the system. Many agricultural system models are of this type, and include the crop, its pests, soil nutrients, and weather conditions, among other factors. Some other types of computer models are described in later sections. In all cases, though the model is in essence specified by the code itself, it is very useful to have some graphical description of the major components of the model. One example is shown in Figure 2. A number of general modeling software packages are designed explicitly to aid construction of computer models through the use of graphical elements. These packages provide users with the capability to rapidly develop and compare models with differing numbers of components, for example, differing species and associated trophic interactions between them, by automatically generating the computer code for the models and allowing users to vary the basic model parameters such as birth rates. Each of these tools has limitations, for example, in the solution methods they employ, but as long as users are aware of these the tools can greatly

Figure 2 Graphical depiction of the major components of an individual-based model for deer.

reduce the time needed to construct computer models with many interacting components.

Limitations of Models

Trade-offs: Generality, Precision, Realism

No single model can do everything. In the process of deciding what components of a system to include, what processes to consider, and what spatial and temporal extent is appropriate, the model excludes part of reality. Modeling is a process of selective ignorance. We decide what to include and what to exclude. Part of the art of modeling is coming to grips with the issue of which details are important and which ones are not. In most cases the process is iterative, with a sequence of different models being tried until a model is arrived at that includes just the essential details necessary to address the problem of concern. Inherent in the process of modeling is that there are criteria by which the model will be evaluated. These criteria might be best chosen prior to model development, based on the objectives for which the model is being constructed.

One view of the trade-offs in constructing a model is that no single model can be simultaneously general, precise, and realistic (Levins, 1968). As **Figure 3** illustrates, these properties may be viewed as points of a triangle. Generality implies that the model may be useful in many different natural systems. A realistic model is one with components, parameters, and variables that are all possible to estimate from observations. A precise model is one that produces quantitative, accurate descriptions of the natural system. Models for theory development, including most of the classical population and community models, are quite general and somewhat realistic, but lack in precision. Descriptive models designed to mimic the response of particular systems tend to be quite precise, slightly realistic, and not at all general. Most regression models

Figure 3 Trade-offs in modeling.

are of this type. They may provide an accurate portrayal of a particular system, for example, winter wheat growth in Nebraska, but are not transferable to other situations such as winter wheat growth in eastern Russia. System simulation models tend to be quite realistic and somewhat precise, but not very general. Control models take up various positions in the figure, depending on the level of precision desired.

Aggregation and Loss of Detail

A factor that affects where a particular model fits into the scheme shown in **Figure 3** is the amount of aggregation included. Natural systems consist of many components that can be lumped together or disaggregated. Population models that use a single variable to represent the whole population inherently ignore the within-population structure (e.g., age and size) or equivalently incorporate assumptions about the distribution of this structure within the population (e.g., stable age distribution). Such a model would not be able to discriminate between a population with mostly small individuals and one with mostly large individuals, unless this within-population structure was assumed to affect the population's growth characteristics in some manner. Aggregation implies a loss of detail that allows consideration of quite general models. Often this then incorporates model parameters that are not at all easily estimated from observations. Examples would be the growth rates in population models and the competition coefficients in community models. The less the aggregation in the model, the more the parameters there tend to be and more data are required in order to estimate them.

Uncertainties: Mechanisms, Data for Parameterization, Biotic and Abiotic Forcing Functions

The modeling process is limited by the information available. There may not be basic agreement on the mechanisms that are critical in the system of concern, so that any particular model includes only some of the mechanisms, or just partial information on these mechanisms. Many population models applied to vertebrates ignore social structure, despite evidence that it is often present in such populations. Excluding some mechanisms in a model may occur due to lack of understanding of the effect of such mechanisms at the scale of

interest for the model. This can give rise to another set of models designed specifically to investigate these effects. So there might be a hierarchy of models, each of which disaggregates some components in order to investigate the potential impacts of uncertainties in these components on the overall model results of particular interest.

Under situations in which the mechanisms are well understood, it may not be possible to accurately estimate model parameters because adequate data are lacking. A variety of statistical methods are designed specifically to determine the optimal choice of parameters in such situations (Hilborn and Mangel, 1997). These methods may take account of parameters estimated either for similar species or for similar locations other than the one being considered. For example, it may be necessary to use observed clutch size distributions for one bird species in application to a similar species about which such information is lacking. Another uncertainty associated with natural system models arises due to the unpredictability of forcing functions such as weather and disturbance. If historical information is available on these functions, this may be used to estimate the stochastic effects of such forcing. Simple ways to incorporate unpredictability of forcing functions would be to determine how the model responds to the maximum and minimum observed values of these forcing functions, and compare this to the model results when using the mean value of the forcing function. This is one form of uncertainty analysis in which a protocol is used to evaluate the impact of uncertainties in model inputs and model structure on the results of the model. Computational methods make it very feasible to evaluate model response to more elaborate and realistic assumptions on forcing by making numerous model simulations under different forcing function assumptions. For example, Fuller *et al.* (2008) evaluate the robustness of Everglade restoration scenarios under diverse assumptions about future rainfall conditions. Various uncertainties limit the detail at which models may be constructed, and thus limit the types of questions that may be addressed using models.

Some Tools of the Trade

Statistical Approaches

Statistical models usually have a descriptive objective rather than a mechanistic one. The parameters within these models are directly estimated by choosing them in a manner that best fits a certain dataset. Thus any particular statistical model is typically not very general in application to different systems. The structure of such models may be useful in a wide variety of different contexts. Regression models, which assume a particular mathematical relationship between variables and assume that errors in the data take a particular form, are widely applied. Numerous regressions have been estimated for species richness as a function of latitude, altitude, and rainfall (Huston, 1994). Discussion of statistical methods applied to estimation of population sizes and densities may be found elsewhere in these volumes.

An alternative view of statistical models is that they are far more than simply descriptive, by providing a method to tease

apart potential impacts of complex interactions from limited observations. This is one of the objectives of hierarchical Bayesian methods in which data on uncontrolled variables are used to estimate the interactions at different levels or scales in a system. This might include determining the relative genetic variability within and between populations, developing methods to combine data from quite different experiments, and analyzing how global change impacts plant diversity through its various effects on CO₂, nitrogen deposition, and changes in precipitation. The idea is to consider a hierarchy of processes in which the probability distribution at one level of the process depends on that of components at other levels. Using conditional probability arguments several times allows a Bayesian updating to build up a complex model from simpler conditional relationships. The posterior distribution can then be quite complex, but is possible to obtain using a Markov Chain Monte Carlo method in which the Markov chain being simulated has the same stationary distribution as the desired posterior distribution from the hierarchical Bayes model. See Clark and Gelfand (2006) for a variety of applications of this methodology to environmental problems.

Dynamic Models

Although many of the traditional models for populations and communities are in the form of dynamical systems (e.g., collections of linked differential or difference equations), often the types of analyses performed for these models are based around equilibrium assumptions. The objective is to find long-term asymptotic behavior. This may be a static equilibrium (e.g., population sizes approach a constant value through time) or a dynamic equilibrium (e.g., population sizes follow repeatable patterns through time; Murray, 2007). While these situations may arise, many models produce behavior that does not have a long-term equilibrium structure. Another key objective is to determine the stability characteristics of any equilibria that arise, in the mathematical sense of determining whether a model that is perturbed from an equilibrium condition will return to it. The dynamics arising in all these models takes account of the basic demographics of the population, as well as interactions with other populations. Adding abiotic conditions such as temperature and rainfall, or adding spatial components, often requires that the analysis be done using numerical simulations. The availability of rapid solution methods for even quite complex dynamical systems has allowed for extensive investigation of the behavior of these models when parameters are not well known. "Parameter sweeps" are particularly simple to perform in parallel using cluster computers, and provide a means to determine how a system is projected to move from one type of dynamical behavior to another as parameters change.

Geographical Information Systems (GIS)

Remote-sensing methods have opened new possibilities for following and modeling the responses of the earth's biota. A key tool that allows the use of such materials is GIS, which enables computers to graphically display the remote-sensing data as two-dimensional maps. Each image may represent one

aspect of an underlying landscape, such as landcover or vegetation type. The image value at any particular location (or pixel) in the map is estimated using models that classify the output of the cameras or the multispectral scanners on satellites into types appropriate for the objective. These models require ground-truthing to ensure that the estimated value for a particular location matches what is actually present. GIS methods allow various spatially explicit components of a landscape to be combined by looking at different map layers (different images measuring different aspects of the landscape). A mathematical function is then applied that averages or applies thresholds to these various components. Estimates of regional and worldwide carbon uptake are obtained using such methods applied to vegetation maps, in which different carbon assimilation values are assigned to different vegetation types, linked with weather maps supplying temperature and rainfall patterns. Many specialized tools are available within standard GIS systems, for example, to follow the movements of individual organisms with remote-sensing tools. Though not yet standardized, temporal GIS methods provide a means to analyze dynamic models across landscapes, and there are 3-D extensions of GIS.

Applications

Habitat Suitability Indices

Habitat Suitability Evaluation Procedures (HEP) are a formalized methodology for impact assessment on wildlife habitat. These are based on Habitat Suitability Index (HSI) models (Verner *et al.*, 1986), which attempt to summarize the site characteristics that affect the utilization of particular habitats by a variety of wildlife species. Numerous HSI models have been constructed, typically consisting of very simple regression-type models. The key habitat variables are often some measure of canopy cover in a variety of classes, diameter classes of trees and shrubs, tree stem densities, area of open water, and distance to forest cover, among others. The objective is to combine these variables, based on extensive field observations done in a correlative manner, to provide overall indices of suitability. HSIs are always indexes with values between zero and one, and they are assumed to be proportional to carrying capacity.

HSIs are based only on local habitat variables; they completely ignore any effects due to species interactions, except those due to indirect effects on related habitat variables. The models ignore the spatial interactions of habitat types across a landscape. This leads to difficulty in situations for which the size, shapes, edge effects, and neighborhood relationships have a greater effect on habitat preference than local forest composition and structure variables. The models also do not take account of the issue of presence/absence of a species, and thus ignore any historical influence on potential local abundance. HSIs are inherently static entities, so any dynamics they produce are driven completely by changes in habitat variables and not by the inherent dynamics and demography in the species being considered. Despite these criticisms, HSIs are among the most commonly used set of ecological models, in part because users realize their limitations and view them as a

simplified tool to summarize a very complicated situation by a single number. Such simplification must result in a loss of information, but a key issue regarding HSIs is whether they indeed can be used as a useful predictor for abundance.

Metapopulation Models

HEP is an attempt to account for the spatial nature of biodiversity by including explicit maps of basic habitat variables. An intermediate approach between models that include all the spatial detail available from maps and those that ignore all spatial aspects of a system is metapopulation models. These models consider a landscape to be split up into a number of localized populations, called subpopulations, with the entire collection of these called a metapopulation. Most of the biotic interactions driving population dynamics occur within the localized subpopulations, but there are exchanges of individuals between these subpopulations. This allows for differing environmental, demographic, genetic, and disease situations to be present in the subpopulations. Depending on the assumptions about transport of individuals between the subpopulations, these can be relatively isolated or closely coupled.

A clear advantage of metapopulation models is the ability to derive analytical results, such as equilibrium and stability behavior, as a function of the within-subpopulation characteristics and the between-subpopulation factors such as movement. The models are particularly appropriate for cases in which a landscape can be reasonably viewed as containing discrete patches of habitat suitable for the population, with the intervening regions not suitable. The level of detail in these models can be quite variable, with the simplest versions just treating subpopulations as either present or absent. More complicated models take account of demographics within each subpopulation or explicit details on the relative spatial locations of each subpopulation that affect movement between them. These can be used for a population viability analysis, in which the probability that the overall population will survive for varying time periods is estimated.

Individual-Based Approaches

Classical ecological modeling approaches include various levels of aggregation in order to simplify the model. An alternative reductionist approach is to take account of differences between individuals within a population, allow the individuals to feed, grow, and interact, and from the aggregated behavior of these individuals build an understanding of population-level responses (Grimm and Railsback, 2005). These individual-based approaches are increasingly common; thanks to advances in computers and the increasing availability of data on behavior and physiology of species of particular interest. The advantages of these approaches include the ability to consider the effect of abiotic factors on populations through their direct impact on individual behavior and growth, to take account explicitly of spatial variation in habitat factors, and to deal with small populations in which individual differences within the population can have great impacts on population-level responses. Disadvantages of

individual-based approaches include the requirement for a great amount of detailed data to realistically simulate individual behaviors, and the typical necessity of making numerous simulations to evaluate any particular response that may arise because of the stochastic nature of the models. The methodology to describe and interpret these models is now becoming standardized and there are readily accessible general tools for constructing these models, NetLogo being one of the more accessible ones.

Future Trends

Multimodeling and Regional Assessment

Natural systems have many interacting components operating at a variety of temporal and spatial extents and requiring differing levels of detail to describe the interactions between them. One historical approach in ecology to model such systems is to break it into a number of compartments (often for different trophic levels, and sometimes with grouping within each trophic level) and consider the dynamics of each compartment with movements of energy, biomass, or nutrients among them. It is quite difficult to make these systems analysis approaches spatially explicit or to link them to GIS. Yet it is now becoming possible to link together a variety of different modeling approaches in order to best utilize the available data, with different resolutions at different trophic levels, and carry this out in a spatially explicit manner. Such multimodels may use very simple models similar to HSLs for some trophic components, more complex dynamical systems for certain populations with mostly very localized interactions, and individual-based models for organisms that move great distances and average over the spatial heterogeneity. One example of such an approach is the Across Trophic Level System Simulation (ATLSS) Project, a multimodel used to estimate the biotic impacts of alternative water management plans on the Everglades of south Florida (DeAngelis *et al.*, 1998).

Building multimodels requires extensive landscape data obtainable from remote-sensing and ground efforts. The approach is inherently dynamic, and thus requires methods to estimate the spatial dynamics of key environmental drivers, or else have available a history of this spatially that can be analyzed statistically. In the Everglades, the major driver is water, and both historical data and detailed hydrologic models are available to provide estimates for scenario evaluations. Without such data, assumptions must be made about the dynamics of the landscape. Continued enhancement of remote-sensing methods and sensor data on individual organisms is providing extensive time series of remotely sensed data to both calibrate multimodels and provide the opportunity to iteratively improve their predictive abilities. For problems at regional spatial extents, such multimodels are a rational method to aid planning while taking account of the best scientific data at the variety of resolutions available.

Behavioral Dynamics of Species of Special Concern

Great strides are being made in improving our understanding of the conservation biology of rare, threatened, and

endangered species throughout the world. In an effort to better estimate the responses of populations of these species, numerous remote-sensing methods have been employed to track the movements of individual organisms. These include tracking devices implanted within or fixed on sampled individuals, which allow explicit location and physiological data (e.g., body temperature) to be obtained regularly and remotely throughout the individual's life. When done for many individuals within a population, it is becoming possible to follow the behavioral dynamics of mixtures of individuals. This includes the ability to ascertain details of mating, territoriality, and aggressive interactions. It is likely in the future that managers concerned with a particular species will be able to observe in real time the movements of many individuals within a population. Then they might apply spatially explicit modeling methods to project the response of the population to particular management alternatives and compare these with optimization models that project the "best" that is possible to do according to some criteria.

Glossary

Alpha diversity The mean effective density of types (such as species) expressed per compositional unit in a dataset. See eqn [15].

Beta diversity The effective number of compositional units in a dataset. See eqn [17].

Compositional unit A virtual subunit that contains as many types (such as species) as the actual subunits do on average, but does not share types with the other virtual subunits. See Figure 2.

Diversity The effective number of types (such as species) into which the entities (such as individuals) that form the dataset of interest have been classified. Also known as “true diversity” and “Hill number.” See Figure 1.

Effective species A virtual species that has the same proportional abundance as the actual species do on average. The number of effective species, or effective number of species, is species diversity. See Figure 1.

Evenness The effective number of types expressed as a proportion of the actual number of types in the dataset. See eqn [9].

Gamma diversity Total effective number of types (such as species) in a dataset. See eqn [10].

Generalized mean with exponent $q - 1$ A general equation that allows deriving different kinds of mean (e.g., arithmetic and geometric) by varying the parameter q . See eqn [2].

Gini–Simpson index An index that quantifies the probability that two entities (such as individuals) drawn at random from the dataset represent different types (such as species). Often used as a diversity index, but not to be confused with diversity itself. See the explanation after eqn [6].

Proportional abundance The abundance (such as the number of individuals) of one type (such as species) expressed as a proportion of total abundance (number of individuals) of all types (species) in the dataset.

Richness The actual number of types (such as species) into which the entities (such as individuals) that form the dataset of interest have been classified.

Shannon entropy An index that quantifies the uncertainty regarding which type (such as species) is picked when one entity (such as individual) is drawn at random from the dataset of interest. Often used as a diversity index, but not to be confused with diversity itself. See eqn [4].

Simpson index An index that quantifies the probability that two entities (such as individuals) drawn at random from the dataset represent the same type (such as species). Often used as a diversity index, but not to be confused with diversity itself. See the explanation after eqn [6].

Species turnover A measure of the amount by which the species composition changes among subunits in the dataset.

Introduction

Confusion around the concept “diversity” has long hampered accurate communication among researchers. For example, Hurlbert (1971) lamented: “The term ‘species diversity’ has been defined in such various and disparate ways that it now conveys no information other than ‘something to do with community structure’; species diversity has become a non-concept.” Hill (1973) argued for a logically coherent definition of diversity, which implies making a distinction between diversity itself and different kinds of diversity indices. Unfortunately, ecologists have continued to treat diversity indices as if they measured the same thing as diversity itself does, which makes much of the diversity literature very difficult to understand and interpret in a coherent way.

In recent years, awareness of the problems caused by inconsistent and often contradictory use of terminology has increased. Since Jost (2006, 2007) revived Hill’s definition of diversity, it has become possible to appreciate that the concept of diversity is actually quite simple (Tuomisto, 2010a, b, c, 2011). The simplicity emerges from three main sources. Firstly, the concepts become less ambiguous when an explicit difference is made between diversity itself and diversity indices.

An index of something is just a surrogate for the thing itself, and for an index to be useful, it needs to be clear what it is an index of. This necessitates an unambiguous definition of diversity itself. Secondly, Hill’s definition of diversity is understandable in simple, everyday terms, which makes diversity a much less abstract concept than ecologists have often thought. Thirdly, separating the conceptual problem of defining diversity from the practical problem of deciding how to adequately quantify diversity for a community of interest allows a clearer view on the issue. As a result, it has become a feasible goal to reach a consistent terminology for diversity and related concepts.

Before getting into the details, it is worth noting that diversity can be quantified for any dataset for which observed entities have been classified into types. The entities are often individuals, but with organisms whose individuals are difficult to delimit (such as clonal plants or colonial animals), the entities may also be something else, such as ramets, colonies, or units of cover or biomass.

If species diversity is of interest, the types into which the entities are classified are species. In other cases, the entities may be classified into, for example, genera, families, haplotypes, or functional types. To calculate the diversity of the

Figure 1 The calculation of species richness and species diversity in a small dataset consisting of a single tree plot. Species richness is the number of boxes (the set at left) needed to place all individuals into a box with an appropriate species name. Species diversity is the number of new boxes needed (the sets at right) to place all individuals into a box such that each box receives as many individuals (or as large a proportion of all individuals) as the named species have, on average (only a part of the last new box may be needed). The measure of "average" here is the weighted generalized mean with exponent $q - 1$. This can be calculated by first taking the weighted mean of the absolute species abundances (6, 7.7, and 9.1 individuals for $q=0$, 1, and 2, respectively) and then dividing this by total abundance (18 individuals). Equally well, one can calculate the weighted mean of the proportional abundances directly (as shown in the equation of the generalized mean; R is the number of actual named species and p_i is the proportional abundance of the i th species). Species diversity qD equals the inverse of mean p_i , and it is the effective number of species (the number of equally abundant species that would give the observed mean species abundance). The measurement unit is hence actual species (sp) in the case of richness and effective species (sp_E) in the case of diversity. Reproduced from Tuomisto H (2011) Commentary: Do we have a consistent terminology for species diversity? Yes, if we choose to use it. *Oecologia* 167: 903–911, with permission from Springer.

dataset, all that is needed is knowledge of the proportional abundance of each of the relevant types within the dataset. Species richness is related to species diversity, but is not the same thing: it does not take the proportional abundances into account. In this article, the letter D will be used for diversity and the letter R for richness. The traditional notation S refers specifically to species richness and is not used here to avoid restricting the discussion to this specific kind of richness. For simplicity, this article is nonetheless written in terms of species richness and species diversity, but the same logic applies to any types or categories of interest.

Defining Diversity

Species richness (R) of a dataset can be defined simply as the number of species names in the species list that is obtained after every individual (or other entity) that belongs to the dataset has been identified to species. This can be called the actual number of species. Species diversity (D) is a more complicated concept, because it takes into account not only how many species the dataset contains but also their relative abundances. This can be done in many different ways, which

has led to a variety of definitions for the concept "diversity" (reviewed in Peet, 1974; Magurran, 2004; Jost, 2006, 2007; Gauthier *et al.*, 2010; Tuomisto, 2010a). In the interest of accurate scientific communication, "species diversity" is here defined as the effective number of species, following Hill (1973).

This definition of diversity D can be derived as follows. Let us first define the proportional abundance of species i in the dataset to equal $p_i = m_i/m$, where m_i is the absolute abundance of species i and m is the total abundance of all species in the dataset. For simplicity, abundance is here treated as the number of individuals, but the same principles also apply when other units of abundance are used (e.g., grams of biomass or square meters of cover). When all species are equally abundant, then $m = m_i R$, and the proportional abundance p_i of each species equals $m_i/(m_i R)$, which simplifies to the inverse of richness $1/R$. The mean proportional species abundance then also equals $1/R$. When all species are not equally abundant, some of them have a larger and others a smaller proportional abundance, but the mean of the proportional abundances is nevertheless a single value $\bar{p}_i$, which can also be expressed as $\bar{m}_i/(\bar{m}_i D) = 1/D$. Species diversity D can hereby be defined as the number of equally abundant species that would be needed

to obtain the same mean proportional species abundance as that observed in the dataset of interest. This is the effective number of species (MacArthur, 1964, 1965; Hill, 1973; Routledge, 1979; Figure 1).

A mean can be calculated in several different ways, which has implications for the quantification of diversity. The different kinds of mean yield different values when applied to the same dataset, so the diversities based on them also obtain different values. Hill's (1973) definition of diversity can be written in the general form

$${}^qD = 1/{}^q\bar{p}_i \quad [1]$$

Here qD is diversity of order q , and ${}^q\bar{p}_i$ is the corresponding mean of the proportional species abundances. The mean here is the weighted generalized mean with exponent $q-1$, which is calculated as

$${}^q\bar{p}_i = \sqrt[q-1]{\sum_{i=1}^R p_i p_i^{q-1}} \quad [2]$$

When calculating the mean, each p_i value is nominally weighted (i.e., multiplied) by itself, but the exponent $q-1$ modifies the weighting. When $q=1$, the actual weights equal the nominal weights, which implies that each species contributes to the value of the mean in proportion to the amount of data (e.g., number of individuals) it contributed to the dataset. In other words, each individual has the same weight no matter which species it belongs to: each individual pulls the mean toward the p_i value of its own species by exactly the same weight irrespective of its species identity. Smaller values of q ($q < 1$) deemphasize the abundance differences among species. This gives rare species more weight than implied by their p_i , and individuals of rare species hence pull the mean toward the p_i value of their own species with more weight than individuals of abundant species do. Conversely, larger values ($q > 1$) exaggerate the abundance differences among species and hence give abundant species (and individuals belonging to them) disproportionate weight. Specific values of q correspond to familiar kinds of means (Hill, 1973):

$q \rightarrow -\infty$	minimum p_i value
$q=0$	harmonic mean = $1 / \sum_{i=1}^R p_i / p_i$
$q=1$	geometric mean = $\prod_{i=1}^R p_i^{p_i}$
$q=2$	arithmetic mean = $\sum_{i=1}^R p_i p_i$
$q \rightarrow \infty$	maximum p_i value

In practice, the parameter q determines where the mean proportional species abundance lands within the possible range between the minimum and the maximum p_i observed in the dataset (see Figure 1 for a numerical example).

By combining eqns [1] and [2], the definition of diversity can be written:

$${}^qD = 1 / \sqrt[q-1]{\sum_{i=1}^R p_i p_i^{q-1}} \quad [3]$$

If all p_i values are identical in a dataset, the number of effective species (qD) in that dataset equals the number of actual species (R) no matter which value of q is chosen. If different species have different p_i values in a dataset, increasing q causes mean p_i to increase and hence diversity qD to decrease for that dataset. At $q=0$, the number of effective species (0D) equals the number of actual species (R) even when all species are not equally abundant. At $q=1$, diversity equals the exponential of the Shannon index, and at $q=2$, diversity equals the inverse of the Simpson index (these diversity indices will be discussed in more detail in the Diversity Indices section). Negative values of q cause the number of effective species to exceed the number of actual species (${}^qD > R$), and positive values of q cause the number of actual species to exceed the number of effective species ($R > {}^qD$).

In diversity studies, q is usually limited to nonnegative values. This is because increasing the weight given to the rarest species makes the mean proportional species abundance more dependent on the total size of the dataset. The rarest species in a dataset are often singletons (represented by a single individual), and their proportional abundance is $1/m$. As q approaches negative infinity, the mean of the proportional abundances approaches this minimum value, and the effective number of species therefore approaches m , that is, the total number of individuals in the dataset. It is difficult to think of practical applications where this property would be desirable in a diversity measure, and setting the restriction $q \geq 0$ ensures it does not cause problems of interpretation.

Obviously, qD can obtain very different values depending on the chosen value of the parameter q . However, the conceptual interpretation of qD does not change with q : it always quantifies the effective number of species (or other types of interest) in the dataset. Depending on the questions at hand, it might be appropriate to choose just a single kind of mean to calculate qD , or several kinds of mean could be used in parallel (by choosing different values for the parameter q) to explore how the effective number of species varies when rare versus abundant species are emphasized in different ways (e.g., Ricotta and Avena, 2002; Kindt *et al.*, 2006; Tuomisto, in press).

The concept of diversity as an effective number of types was apparently first used in ecology by MacArthur (1964, 1965), but it was more thoroughly discussed by Hill (1973). Owing to Hill's influential paper on the topic, the diversity values have been known as "Hill numbers" (or "Hill's numbers") in the ecological literature. Although some researchers adopted Hill numbers relatively early (e.g., Routledge, 1977, 1979), they have generally been treated as just another diversity index (e.g., Magurran, 2004). However, Jost (2006, 2007, 2009) has argued that the effective number of types should be used as the only definition of diversity and proposed to call it "true diversity" to distinguish it from diversity indices that represent phenomena other than a count of effective species. This narrow definition of "diversity" is gaining in influence, because it considerably clarifies communication about diversity issues (e.g., Gregorius and Gillet, 2008; de Bello *et al.*, 2010; Gauthier *et al.*, 2010; Gregorius, 2010; Tuomisto, 2010a, b, c, 2011; Jurasinski and Koch, 2011; Moreno and Rodríguez, 2011).

It can be noted that the use of the word "true" in "true diversity" is analogous to its use in "true bugs" (Tuomisto,

2011). In both cases, the word is used as a synonym of “in the narrow sense.” In the case of bugs, “true” indicates that the interest is in insects of the monophyletic order Heteroptera, rather than in the polyphyletic assemblage consisting of any insect-like animals and pathogenic microorganisms, which are also called “bugs” in everyday contexts. In the case of diversity, “true” indicates that the interest is in the effective number of types, rather than in the conceptually heterogeneous group of phenomena consisting of numbers of types, entropies, probabilities, and differences, which have also been called “diversity” in the ecological literature. Gregorius (2010) used the term “explicit diversity” instead of “true diversity,” possibly because the latter has raised negative reactions as some researchers have misinterpreted “true” to mean “best for any purpose” (Hoffmann and Hoffmann, 2008; Anderson *et al.*, 2011; Gorelick, 2011).

The greater the largest p_i values in a given dataset, the larger the mean p_i and hence the smaller the number of equally abundant species that would be needed to obtain the same mean p_i value. These hypothetical, equally abundant species can be called effective species (${}^{\text{sp}}_E$), and they are the unit of measurement of species diversity qD (note the use of the superscript q to specify which mean is used). In contrast, species richness R is measured in units of actual species (sp; Tuomisto, 2010a, c). When the individuals (or other observed entities) are classified into types other than species (such as genera, families, functional types, haplotypes, or size classes), the measurement units of richness and diversity change accordingly (e.g., actual and effective genera, respectively).

Both richness and diversity follow the important replication principle: if each of the original species is replicated to form r different species, each of which has the same absolute abundance as the original, both richness and diversity of the dataset increase to r times their original values (Hill, 1973; Jost, 2006, 2007). The replication principle corresponds to an intuitive sense of how diversity is expected to behave. The traditional diversity indices (such as the Shannon and Gini–Simpson indices) do not follow the replication principle, which is one reason why their values are often misinterpreted (Jost, 2006, 2007, 2009).

Practical Issues in Quantifying Diversity

Often ecologists are interested in the species richness or diversity of a community, but are able to sample only a tiny fraction of the individuals belonging to that community. Since any one of the unseen individuals could represent a species not recorded in the sample, the species richness of the community is generally (and often considerably) underestimated by the recorded data. Therefore, richness and diversity values that are accurate for an existing dataset provide no more than estimates for the community of interest. How accurate such estimates are depends on how representative the dataset is of the community. In general, the more species a community contains, the more individuals need to be observed for the sample to become representative. Different kinds of sampling and data analysis methods can be used to improve the accuracy of the estimate, just as in other situations where results

are extrapolated beyond the actual observations (e.g., Colwell and Coddington, 1994; Plotkin and Muller-Landau, 2002; Chao *et al.*, 2005; Beck and Schwanghart, 2010; Gauthier *et al.*, 2010).

Much of the discussion in the past on how to define diversity has actually focused on how to accurately estimate diversity for a community of interest from a sample of that community. For example, it has often been recommended that diversity is best measured using diversity indices that stabilize at small sample sizes (e.g., Lande, 1996; Magurran, 2004; Beck and Schwanghart, 2010). By this criterion, species richness is a very bad index of diversity, the Shannon index clearly better, and the Simpson index superior to both. However, the conceptual definition of a term should not depend on context-specific details such as sampling decisions, the ease of measurement, or the questions of interest in a particular study. Consider observing a mixed-species flock of birds. How the concept of “species diversity” is defined should not depend on how difficult it is to decide which individuals belong to the flock and which species each individual belongs to. Similarly, how the concept of “volume” is defined should not depend on how difficult it is to decide where the physical limits of the flock are. Of course, such decisions determine whether the measurement result is appropriate and sufficiently accurate for the intended purpose, but this is a separate issue that has no bearing on which phenomenon is represented by the variable to be measured (whether diversity or volume).

In this article, the focus is on conceptual definitions, so richness and diversity will be treated simply as properties of an existing dataset (see also Smith and Wilson, 1996; Gregorius and Gillet, 2008; Tuomisto, 2010a, b, c). Before diversity and richness can be quantified, a decision has to be made on the limits of the dataset, that is, which individuals (or other entities) belong to it. Every different set of individuals in effect corresponds to a different dataset and consequently may yield different richness and diversity values.

Each individual that is added to a dataset may represent a species that was not yet present in the dataset before. Therefore, drawing meaningful ecological conclusions from comparisons of richness and diversity values among datasets necessitates that the methods by which individuals have been selected for the datasets are comparable, which in practice implies that sampling efforts must have been standardized across the datasets in an appropriate way (Gotelli and Colwell, 2001; Gauthier *et al.*, 2010; Tuomisto, 2010b). For example, bird inventories might be based on making observations in a fixed observation point either for a predefined amount of time or until a predefined number of individuals has been recorded. Tree inventories could be based on recording all stems of a predefined minimum diameter in a plot of a predefined shape and surface area, or on recording a predefined number of stems using some plotless method. Inventory of marine benthic fauna could be based on animals captured by sieving cores of a specific volume through a mesh of a specific size.

If the communities of interest vary widely in species diversity, standardizing relative sampling effort (representativeness or coverage) may sometimes be more important than standardizing absolute sampling effort (e.g., number of individuals). A relevant measure of sampling effort in such cases would pay attention to species accumulation curves or the

proportion of singletons in the data (Good and Toulmin, 1956).

If all individuals within a fixed surface area have not actually been observed and included in the dataset, then surface area cannot be used as a measure of sampling effort. For example, the nominal sampling unit size in macroecological studies may be fixed (e.g., 50 km by 50 km grid cells), but the actual sampling effort invested in each sampling unit (e.g., time spent in the field or number of individuals observed) can vary by several orders of magnitude among grid cells. In such cases, the observed patterns in richness and diversity may depend more on the uneven distribution of field work effort than on any ecologically interesting phenomenon.

In addition to defining the limits of the dataset, it is important to define how abundance is measured. Many different ways are possible and justifiable. Possible measures include the number of individuals, the number of stems or ramets, biomass, basal area, volume, or the percentage of surface cover. Obviously, if the size of individuals varies (as it generally does), the number of individuals and biomass can be expected to give different diversity values even when calculated for the same dataset, and diversity values based on different abundance measures are therefore not comparable across datasets.

Both richness and diversity also depend on how the individuals (or other observed entities) are classified into types. A lumpers and a splitter will rarely report the same species richness for a given dataset, and family richness can change dramatically depending on which family circumscriptions are used. Consequently, interpretation of results for richness and diversity requires careful specification of the classification that was used. Comparing richness or diversity values among datasets is meaningful only if all of them are based on the same classification. For example, if one dataset has identified tropical trees to the species level and another only to the genus level, comparing richness and diversity values between them yields meaningless and misleading ecological conclusions.

Diversity Indices

Shannon Index

Several indices of diversity have been popular in ecology (reviewed in Magurran, 2004; Gauthier *et al.*, 2010). Until recently, too little attention has been paid to the fundamental conceptual differences among those indices. Consequently, the term “diversity” has been used in several conceptually different ways in the ecological literature, as indices of diversity have been equated with diversity itself (Jost, 2006, 2007; Tuomisto, 2010a, c).

The most popular diversity index by far in the ecological literature has been the Shannon entropy H' (Shannon, 1948):

$$H' = - \sum_{i=1}^R p_i \log p_i = \log(^1D) \quad [4]$$

This measure is also known as the Shannon index, the Shannon–Weaver index, the Shannon–Wiener index, the Shannon–Weiner index, and (confusingly) the Shannon diversity. The Shannon entropy does not quantify species

diversity (the effective number of species) but the uncertainty in the species identity of an individual that is picked at random from the dataset. The measurement unit of Shannon entropy depends on the base of the logarithm and can be, for example, bits, nats, or decits when using log bases 2, e , and 10, respectively. Taking the exponential of the Shannon entropy recovers true diversity; that is, $^1D = \exp(H')$.

The Shannon entropy is a special case for $q=1$ of the Rényi entropy (Rényi, 1960; Tuomisto, 2010a)

$$^qH' = \log(^qD) = \log(1/\sum p_i^q) \quad [5]$$

Here the value of q defines how the probability of choosing a particular individual is affected by the abundance of the species it belongs to. When $q=1$, each individual has the same probability of being chosen, and hence the probability that the chosen individual represents species i equals p_i . When $q=0$, each species has the same probability of being chosen irrespective of its proportional abundance. The probability that the chosen individual belongs to the most abundant species of the dataset increases monotonically with increasing q . With sufficiently large q , the chosen individual almost certainly belongs to the single most abundant species in the dataset, which has proportional abundance p_{imax} . The uncertainty in the species identity of the randomly chosen individual (Rényi entropy) hence decreases asymptotically toward $\log(1/p_{\text{imax}})$ as q increases toward infinity. This parallels the behavior of the mean proportional species abundance, which increases toward the abundance of the most abundant species as q increases (see explanation after eqn [2]).

Simpson Index and Gini–Simpson Index

Equation (3) is usually written in the form

$$^qD = \left(\sum_{i=1}^R p_i^q \right)^{1/(1-q)} \quad [6]$$

The term inside the parentheses ($^qD^{1-q}$), known as the “basic sum,” has often been used as a diversity index. When $q=2$, the basic sum equals the Simpson index $\sum_{i=1}^R p_i^2$ (Simpson, 1949; Hill, 1973; Jost, 2006, 2007; Tuomisto, 2010a), which quantifies the probability that two individuals picked at random from the dataset (with replacement) represent the same species. Hurlbert (1971) called this the probability of interspecific encounter (PIE, which can also be calculated, in a slightly modified form, to account for not replacing the first individual before choosing the second). The Simpson index decreases as the species richness of a dataset increases, so in itself it is an impractical index of diversity. A popular transformation of the Simpson index that increases with increasing richness is the Gini–Simpson index, which is obtained by subtracting the Simpson index from unity. The Gini–Simpson index quantifies the probability that two individuals picked at random from the dataset (with replacement) represent different species.

Another transformation of the Simpson index that also increases with increasing richness is its inverse. Although less popular as a diversity index than the Gini–Simpson index, the inverse Simpson index actually equals 2D , that is, true diversity of order 2. In other words, the Simpson index itself represents

the weighted arithmetic mean of the proportional species abundances, rather than an effective number of species.

The Gini–Simpson index is a special case of an entropy that is known in ecology as the Tsallis or HCDT entropy (Jost, 2006; Mendes *et al.*, 2008). This entropy can be expressed as

$${}^qT = (1 - {}^qD^{1-q}) / (q - 1) \quad [7]$$

The HCDT entropy is a simple transformation of the basic sum, and its value is related to the probability that q individuals chosen at random from the dataset (with replacement) represent at least two different species.

From eqns [3] and [6] it can be seen that the basic sum is just an intermediate step in calculating mean proportional species abundance and its inverse, true diversity. Therefore, using the basic sum to derive an index of diversity is unnecessary; diversity itself is just as easy to calculate as the diversity index, and the risk of misinterpreting the results is diminished if the variable that is reported represents the actual phenomenon of interest rather than a surrogate (or transformation) thereof (Tuomisto, 2010c).

Partitioning Diversity

Multiplicative Partitioning: Richness $\times$ Evenness

Species diversity is traditionally thought to consist of two independent components, richness and evenness (e.g., Peet, 1974; Alatalo, 1981; Smith and Wilson, 1996; Magurran, 2004; Kindt *et al.*, 2006; Mendes *et al.*, 2008; Jost, 2010). One way to combine components that represent different phenomena is by using multiplication, which in this case leads to the following partitioning of diversity (Jost, 2010; alternative evenness concepts are reviewed in Tuomisto, in press):

$$\text{diversity} = \text{richness} \times \text{evenness} \quad [8]$$

Since richness and diversity were already defined in the Defining Diversity section, evenness can be defined as

$${}^qE = {}^qD / R \quad [9]$$

Because richness is based on presence–absence data and hence does not depend on the proportional species abundances p_i , it is not sensitive to the value of q . In contrast, diversity and evenness decrease when the value of q is increased, unless all species (or other types of interest) are equally abundant in the dataset of interest. Consequently, the value of q must always be specified to allow accurate communication about diversity and evenness.

In practice, qE quantifies how many effective types there are for each actual type in the dataset of interest. Species richness is based on presence–absence (binary) data and is measured in units of actual species; species diversity is based on abundance (quantitative) data and is measured in units of effective species. Consequently, the measurement unit of evenness is ${}^q\text{sp}_E/\text{sp}$. The highest possible species evenness ${}^qE_{\max}$ equals $1 {}^q\text{sp}_E/\text{sp}$. This is obtained when there are as many effective species as actual ones, that is, when either all species are equally abundant or $q=0$. When $q>0$, diversity qD decreases toward $1 {}^q\text{sp}_E$ as the proportional abundance of the most

abundant species increases toward unity. As a result, the smallest possible value of evenness ${}^qE_{\min}$ is $(1 {}^q\text{sp}_E)/R$.

For any given dataset, small values of q lead to higher evenness than large values of q . This follows directly from the fact that diversity decreases when q increases, but richness does not change (see Defining Diversity). Different kinds of species abundance distribution lead to different trajectories of diversity qD , and hence of evenness qE , when these are plotted as a function of q (Ricotta and Avena, 2002; Kindt *et al.*, 2006; Jost, 2010; Tuomisto, in press). Graphs showing qE and qD against q provide complementary insights for comparing datasets that differ in R .

Multiplicative Partitioning: Alpha $\times$ Beta

The General Principle

When Whittaker (1960) coined the terms alpha, beta, and gamma diversity, his intention was to understand the species diversity in a landscape (gamma diversity) as the combined result of two different phenomena, namely, the species diversity at a more local scale (alpha diversity) and the compositional heterogeneity among localities (beta diversity). Whittaker explored several approaches to quantifying compositional heterogeneity, and quite some confusion has resulted because he referred to all of them as “beta diversity.” Other researchers have further expanded the circumscription of beta diversity, such that the term has been used to refer to more than 30 distinct phenomena in the ecological literature (e.g., Wilson and Shmida, 1984; Vellend, 2001; Koleff *et al.*, 2003; Jurasinski *et al.*, 2009; Tuomisto, 2010a, b; Anderson *et al.*, 2011).

Some of these “beta diversities” are not mathematically derived from alpha and gamma diversity in any way, and the values of many are uncorrelated with each other. Although most of the resulting measures are useful in themselves, each one of them quantifies a different phenomenon and is therefore relevant for addressing different ecological questions (conceptual differences among the measures are reviewed in Tuomisto, 2010a, b). Confusion among these concepts – because they are referred to by the same name – has caused many unwarranted comparisons among studies and incorrect inferences from data.

Whittaker (1960) did write that the simplest definition of beta diversity is $\beta = \gamma/\alpha$. This corresponds to the multiplicative partitioning of gamma diversity $\gamma = \alpha_d \beta_{Md}$. Subscript “M” is added to specify that the components come from a multiplicative partitioning, and subscript “d” to indicate that their measurement units correspond to the types whose diversity in the dataset is being quantified (notation as in Tuomisto, 2010a). This classical partitioning of diversity has been one of the most widely used definitions of beta diversity in ecological studies, because it yields alpha and beta diversities that are conceptually and numerically independent of each other (e.g., Routledge, 1977, 1979; Vellend, 2001; Jost, 2007; de Bello *et al.*, 2010; Tuomisto, 2010a, c, 2011).

Gamma diversity is conceptually the simplest one of the three diversities: it is the total species diversity observed in the dataset of interest. The dataset may or may not represent a landscape, but whether it does is irrelevant for the definition of the concepts. To quantify gamma diversity, only one

classification within the dataset of interest is needed, namely, the classification of its individuals into species. This classification was already used in the Defining Diversity section, and it can be called the gamma classification (Tuomisto, 2010a). Gamma diversity can hence be defined as the diversity in relation to the gamma classification and identified by adding the subscript γ to eqn [1]:

$${}^qD_\gamma = 1/{}^q\bar{p}_i \quad [10]$$

The richness in relation to the gamma classification, that is, the total number of actual species in the dataset of interest, can be called gamma richness R_γ . The symbols α , β , and γ have been used to refer to both the diversity components and the corresponding richness components, and indeed it may be useful to continue using them in this broad sense, when the alpha, beta, and gamma components are discussed in general terms without specifying whether the interest is in diversity or in richness. However, the distinction between diversity and richness becomes relevant as soon as their values are to be quantified. At this point, more specific notation should be used, such as ${}^qD_\alpha$, ${}^qD_\beta$, and ${}^qD_\gamma$ for the diversity components, and R_α , R_β , and R_γ for the richness components.

Gamma diversity is the total number of effective species in a dataset, and gamma richness is the total number of actual species in the dataset. Both are independent of whether the dataset has been subdivided into smaller units, and if so, how this has been done. In contrast, the alpha and beta components are defined only when the dataset consists of subunits. These subunits may or may not be the same sampling units that were used during the field inventory. It is possible to subdivide a single dataset into subunits in many different ways, and each different subdivision corresponds to different alpha and beta values.

When quantifying alpha and beta diversity or richnesses, each individual is classified not only according to species but also according to subunit. The classification of individuals into subunits has been called the “omega classification” (Tuomisto, 2010a). The richness in relation to the omega classification (omega richness) is the actual number of subunits in the dataset. The diversity in relation to the omega classification (omega diversity) is the effective number of subunits in the dataset (the number of subunits the dataset would get divided into if each subunit received the same number of individuals as the actual subunits have, on average). Alpha diversity or richness is obtained by taking into account both the gamma and the omega classifications simultaneously, but in such a way that the primary interest is in the gamma classification. In other words, each individual is classified both into a species and into a subunit, and the interest is in quantifying the density of species (actual or effective) per subunit (Tuomisto, 2010a, c, 2011).

Exactly the same idea has been expressed by Gregorius (2010) using a different notation. He characterized individuals by two attributes, type (T) and subcollection affiliation (S). The classification of individuals into types corresponds to the gamma classification, and the classification of individuals into subcollections corresponds to the omega classification. Gregorius (2010) used the notation ν_T for gamma diversity (total species diversity in the dataset) and ν_S for omega diversity

(total subunit diversity in the dataset). The earliest definition of gamma diversity in these terms may be that of Routledge (1979), who used the notation N_{ay} (where a has the same meaning as q in ${}^qD_\gamma$).

Alpha, Beta, and Gamma Richness

The richness components are quantified without taking into account species proportional abundances. Alpha richness is simply calculated as the unweighted arithmetic mean of the actual species density values in the subunits

$$R_\alpha = \sum_{j=1}^N \frac{1}{N} R_{xj} \quad [11]$$

Here N is the total number of subunits and R_{xj} is the actual species density (species richness per subunit) in subunit j . The multiplicative partitioning leads to defining beta richness as

$$R_\beta = R_\gamma / R_\alpha \quad [12]$$

This can be interpreted as the number of actual compositional units (CU) in the dataset. The actual (as opposed to effective; see the next section) CU are obtained by rearranging the R_γ actual species of the dataset evenly into new hypothetical subunits such that each subunit receives R_α species. In other words, each compositional unit has the same species density as the original subunits do on average, but does not share species with any other compositional unit. Alpha richness equals the number of actual species per actual compositional unit, which gives it the measurement unit sp/CU (Figure 2; Tuomisto, 2010c, 2011).

Alpha, Beta, and Gamma Diversities

To quantify the diversity components, species proportional abundances need to be taken into account. The proportional abundance of species i that is conditional on the limits of subunit j is $p_{i|j} = m_{ij}/m_j$, where m_{ij} is the number of individuals belonging to species i in subunit j and m_j is the total number of individuals in subunit j . The weighted generalized mean of all these within-subunit proportional abundances is

$${}^q\bar{p}_{i|j} = \sqrt[q-1]{\sum_{j=1}^N \sum_{i=1}^R p_{ij} p_{i|j}^{q-1}} \quad [13]$$

Here N is the number of subunits. The proportion of data that individuals of species i in subunit j contribute to the entire dataset is p_{ij} and this is used as the nominal weight when calculating mean within-subunit proportional abundance. The same mean $p_{i|j}$ can also be expressed as (see Tuomisto, 2010a for derivation)

$${}^q\bar{p}_{i|j} = \sqrt[q-1]{\sum_{j=1}^N w_j \sum_{i=1}^R p_{ij} p_{i|j}^{q-1}} \quad [14]$$

Here the subunit weight $w_j = m_j/m$ equals the proportion of the individuals in the entire dataset contributed by subunit j . Alpha diversity is obtained as the inverse of this mean:

$${}^qD_\alpha = 1/{}^q\bar{p}_{i|j} \quad [15]$$

Figure 2 Two different ways of partitioning the total species diversity of a dataset (true gamma diversity) into two components, given three subunits. The dataset is the same as in **Figure 1**, but only true diversities of order 1 (which are based on the geometric mean of species proportional abundances) are shown for simplicity. Species diversity in each subunit j (1D_j) is calculated in the same way as species diversity in the entire dataset (${}^1D_j = {}^1D_{tot}$; see **Figure 1**). Multiplicative partitioning gives two conceptually and mathematically independent components, namely the effective number of compositionally distinct units (true beta diversity; measurement unit 1CU_E) and the mean effective species density in those units (true alpha diversity). Additive partitioning gives two components that represent the same concept as true gamma diversity does, namely species diversity. One of these components quantifies the mean within-subunit species diversity (${}^1D_{mean}$), and the other (${}^1D_{diff}$) quantifies the total number of effective species that differ (turn over) among all subunits. Reproduced from Figure 2 of Tuomisto H (2011) **Commentary: Do we have a consistent terminology for species diversity?** Yes, if we choose to use it. *Oecologia* 167: 903–911, with permission from Springer Science + Business Media.

This can also be expressed as (see Proof 2 in Tuomisto, 2010a for derivation)

$${}^qD_\alpha = \sqrt[q]{\sum_{j=1}^N w_j ({}^qD_{sj})^{1-q}} \quad [16]$$

This formula expresses the weighted generalized mean with exponent $1 - q$ of the mean effective species densities ${}^qD_{sj}$ in all subunits j . In the notation of Routledge (1979), alpha diversity is N_{az} , and in the notation of Gregorius (2010), it is $\nu_T|S$.

The alpha diversity of Jost (2006, 2007) differs from the alpha diversity defined by eqn [16] in that Jost treated the gamma and the omega classification symmetrically, whereas

eqn [16] considers the gamma classification of primary interest. The differences between the alpha diversity concepts of Routledge and Jost have been discussed by Tuomisto (2010a) and Gregorius (2010). Because Routledge's definition corresponds better with what seemed to be Whittaker's original idea behind diversity partitioning, it is followed throughout this article.

The multiplicative partitioning leads to defining beta diversity as

$${}^qD_\beta = {}^qD_\gamma / {}^qD_\alpha \quad [17]$$

This ratio can be interpreted as the number of effective compositional units (qCU_E). An effective compositional unit is a hypothetical subunit that has the same number (and density) of effective species as the original subunits do on average, but

does not share effective species with the other effective compositional units. Alpha diversity equals the mean density of effective species as expressed per effective compositional unit, which gives it the measurement unit ${}^q\text{spE}/{}^q\text{CU}_E$ (Figure 2; Tuomisto, 2010a, c, 2011). In the notation of Routledge (1979), beta diversity is $N_{\alpha\beta}$ and in the notation of Gregorius (2010), it is N_{eS} .

Properties of Beta Richness and Beta Diversity

In any dataset, there must be at least one compositional unit (both actual and effective), so $R_\beta \geq 1 \text{ CU}$ and ${}^qD_\beta \geq 1 {}^q\text{CU}_E$. Similarly, the total number of species (both actual and effective) in the dataset must be at least as large as the mean number of species per subunit, so $R_\gamma \geq R_\alpha$ and ${}^qD_\gamma \geq {}^qD_\alpha$. Some researchers have complained that the latter condition does not always hold (Gadagkar, 1989; Lande, 1996). However, this is an erroneous assertion based on averaging the effective species densities ${}^qD_{\alpha j}$ using the arithmetic mean, which corresponds to $q=0$, even if some other value of q is used in the calculations otherwise. Using the generalized mean with exponent $1-q$ (eqn [16]) correctly gives alpha diversity values that do not exceed gamma diversity for any value of q .

If all species occur in all subunits, beta richness necessarily equals 1 CU. The more the original subunits differ in species composition, the more compositional units are needed at a given species density to accumulate the given total number of species. Beta richness obtains its maximum value of N when none of the actual subunits share any species.

Because beta diversity depends both on species composition and on species abundances, its behavior is more complex than that of beta richness. When the proportional abundances of the species vary among subunits, ${}^qD_\beta$ may exceed $1 {}^q\text{CU}_E$ even if all species occur in all subunits. Similarly, when no species are shared among subunits, ${}^qD_\beta$ may be either smaller or larger than N . Beta diversity is constrained to the fixed range of $[1, N]$ only when either $q=1$ or the nominal weights w_j in eqn [16] are equal for all subunits j (Gregorius, 2010; Tuomisto, 2010a). Nominal subunit weights are equal when, for example, sampling effort has been standardized to the same number of individuals in all subunits, or when abundances are recorded as percentages that sum to 100% in each subunit.

Increasing the value of q makes ${}^qD_\beta$ more sensitive to the variation among subunits in the proportional abundances of species and less sensitive to variation in species composition. Therefore, changing within-subunit species proportional abundances without changing presence-absence patterns has no effect on ${}^0D_\beta$, and changing species composition without changing the proportional abundance of the single most abundant species has no effect on ${}^\infty D_\beta$ (Tuomisto, 2010a).

Beta richness and beta diversity can be thought of as the richness and diversity in relation to the beta classification. Here the entities of interest are species (actual or effective, respectively) that are classified into compositional units (actual or effective, respectively; compare with the classification of individuals into actual or effective species in Figure 1). Alpha richness and alpha diversity, in turn, correspond to the density of richness and diversity in relation to the gamma classification that is conditional on the limits set by the beta

classification. This combined classification can be called the alpha classification.

Whittaker (1977) referred to α and γ as inventory diversity and to β as differentiation diversity, which has since become a common practice (e.g., Magurran, 2004; Jurasinski *et al.*, 2009). Some researchers have even argued that beta diversity should not be called diversity at all (e.g., Lande, 1996; Kiflawi and Spencer, 2004; Gregorius and Gillet, 2008). However, true beta diversity ${}^qD_\beta$ is the effective number of compositional units, which conforms with the general definition of diversity just as well as the effective number of species does.

Alpha, beta, and gamma diversities are conceptually similar in that each quantifies the effective number of types in a dataset according to a specific kind of classification of the entities that constitute that dataset. The three differ in two ways. Firstly, they classify different entities: individuals in alpha and gamma diversities versus effective species in beta diversity. Secondly, they quantify the relevant diversity at a different level: as a total diversity in the entire dataset in beta and gamma diversities versus a mean density of diversity as expressed per effective compositional unit. This conceptual similarity to ${}^qD_\alpha$ and especially ${}^qD_\gamma$ justifies singling ${}^qD_\beta$ out as the sole measure of true beta diversity and recommending that all other things that have been referred to as “beta diversity” in the past be called something else in the future (Jost, 2006, 2007; Tuomisto, 2010a, b, c, 2011).

Additive Partitioning: Alpha + Beta

Absolute Species Turnover

Lande (1996) proposed defining beta diversity as the difference rather than the ratio of gamma to alpha diversity, which leads to the equation

$$\beta_{At} = \gamma - \alpha_t \quad [18]$$

This approach corresponds to partitioning gamma diversity into additive components $\gamma = \alpha_t + \beta_{At}$. The subscript “A” specifies that the beta component arises from additive partitioning, which is important because it differs from the beta component of the multiplicative partitioning β_{Md} both conceptually and in its numerical value. The subscript “t” specifies that the components relate to species turnover, which affects their measurement units: all components in the additive partitioning have the same measurement unit, namely species (actual species in the case of richness and effective species in the case of diversity).

Lande (1996) borrowed the additive approach from MacArthur (1964, 1965), who had used it with Shannon entropies. However, MacArthur applied the exponential function to the entropies before interpreting the results, and therefore he actually followed Whittaker’s multiplicative approach with true diversities at $q=1$. In contrast, Lande used and interpreted the raw values of different diversity indices, and therefore the components obtained from his partitioning correspond to conceptually different phenomena for each different diversity index (see Tuomisto, 2010a for more detailed interpretations and discussion). The interpretations provided in this article are all based on the assumption that any diversity indices are converted to the corresponding

effective numbers of types before being subjected to additive partitioning.

The additive alpha component expresses how many species there are, on average, in one subunit, and the additive beta component expresses how many of the species in the dataset do not fit within the limits of the average subunit. In other words, both components quantify a count of species (i.e., the types based on the gamma classification), but they do so for different subsets of the data (an average subunit vs. the rest). In contrast, both multiplicative components (α_d and β_{Md}) give a measure that describes the entire dataset, but they differ in that each is based on a different classification (the alpha or the beta classification, respectively; Tuomisto, 2010a, c). In addition, α_d is conceptually a density measure (density of types per subunit), which differs from β_{Md} , β_{At} , α_t , and γ , all of which are simply counts of types.

If not all observed species are present in all subunits, there will be change in species composition, or species turnover, among subunits. Therefore, β_{At} can be interpreted as a measure of total species turnover in the dataset: if one were to start from one (actual or effective) compositional unit and walk through all the other compositional units, β_{At} would indicate how many (actual or effective) species are swapped for a new species along the way. Conceptually, every new species one encounters when moving to a new compositional unit equals half a species turned over, as does every old species that drops out. The additive beta component has recently become widely used in ecological studies (e.g., Veech *et al.*, 2002; Kiflawi and Spencer, 2004; Ricotta, 2008; de Bello *et al.*, 2010). Unfortunately, many studies refer to species turnover as “beta diversity,” even though a count of species that change is both conceptually and numerically very different from a count of compositional units.

Equation (18) does not differentiate between presence-absence data (richness) and abundance data (diversity), and using the notation β for both species turnover and true beta diversity easily leads to confusing them. When the interest is in the turnover of actual species (actual species turnover), a more explicit notation is

$$R_{diff} = R_{tot} - R_{mean} \quad [19]$$

Here the subscript “tot” refers to the total richness in the dataset, “mean” to the mean richness in the subunits, and “diff” to the difference between the total and the mean. The relevant mean here is the unweighted arithmetic mean. All components of the additive partitioning are based on the gamma classification, so all of them could have subscript γ . R_{tot} hence equals R_γ , but in the additive partitioning the components differ in which part of the dataset they refer to, rather than in which classification they are based on, so the subscript “ γ ” is omitted to simplify the notation. When the interest is in the turnover of effective species (effective species turnover), the equation can be written as

$${}^qD_{diff} = {}^qD_{tot} - {}^qD_{mean} \quad [20]$$

The relevant mean here is the weighted generalized mean with exponent $1 - q$ (calculated as in eqn [16]).

As with the multiplicative partitioning, the components of the additive partitioning behave in different ways depending on whether they are components of richness or of diversity.

When all species are present in all subunits, R_{diff} invariably takes the value zero. In contrast, ${}^qD_{diff}$ does so only when either each species also has a constant abundance in all subunits, or when q is sufficiently large and the most abundant species is the same and has the same proportional abundance in all subunits.

The upper limit of absolute species turnover in a dataset depends both on the number of subunits N and on the mean species count within the subunits. If no subunits share any species, actual species turnover R_{diff} necessarily takes the value $(N - 1)R_{mean}$. In the same situation, effective species turnover ${}^qD_{diff}$ takes the value $(N - 1){}^qD_{mean}$ only if either all subunit weights are equal (i.e., all subunits contain the same abundance) or $q = 1$ (see eqn [16]). Otherwise, the value that ${}^qD_{diff}$ takes when no subunits share any species cannot be predicted in advance, because it depends on dataset properties (Tuomisto, 2010a, c).

Whittaker's Species Turnover

In many cases, it is useful to quantify species turnover in relative terms, such that its value does not depend on the absolute number of species involved. Whittaker (1972) developed such a species turnover measure by subtracting unity from the value of the multiplicative beta component. The same measure, Whittaker's species turnover, can be obtained by dividing the additive beta component by the additive alpha component (notation from Tuomisto, 2010a; see also Kiflawi and Spencer, 2004, but note that β_M refers to both β_{Mt} and β_{Mt-1} in their text):

$$\beta_{Mt-1} = \beta_{At}/\alpha_t = (\gamma - \alpha_t)/\alpha_t = \gamma/\alpha_t - 1 = \beta_{Mt} - 1 \quad [21]$$

Here β_{Mt} has the same numerical value as true beta diversity β_{Md} does, but the two differ in that β_{Mt} is unitless (since γ and α_t have the same measurement unit).

When the interest is in presence-absence data, Whittaker's actual species turnover can be expressed more explicitly as

$$R'_W = (R_{tot} - R_{mean})/R_{mean} = R_{tot}/R_{mean} - 1 \quad [22]$$

The prime is added to specify that this is a relativized measure of richness; that is, one richness is expressed in multiples of another richness, which yields a unitless value. Subscript “W” refers to Whittaker's approach. When the interest is in abundance data, Whittaker's effective species turnover can be expressed as

$${}^qD'_W = ({}^qD_{tot} - {}^qD_{mean})/{}^qD_{mean} = {}^qD_{tot}/{}^qD_{mean} - 1 \quad [23]$$

Whittaker's turnover measures express species turnover among the compositional units of the dataset in multiples of the within-unit species count (actual or effective). In other words, these measures quantify how many times the entire species composition turns over among the compositional units, rather than the number of species that turn over.

Whittaker's species turnover and absolute species turnover behave in a similar way in that both obtain their minimum and maximum values under the same conditions, but the numerical values of the actual species turnover measures differ by factor R_{mean} and those of effective species turnover differ by factor ${}^qD_{mean}$. As a result, the maximum value of Whittaker's actual species turnover is $N - 1$, which is obtained when none of the N subunits share any species. The maximum value of

Whittaker's effective species turnover is also $N - 1$, if nominal subunit weights are equal or $q = 1$. In both cases, the values are independent of how many species are involved. This allows comparing compositional heterogeneity among datasets in such a way that the comparisons are not confounded by differences in species richness or diversity. Since the absolute species turnover measures (R_{diff} and ${}^qD_{\text{diff}}$) do depend on the absolute number of species (actual or effective, respectively), they are not monotonically related to the corresponding Whittaker's species turnover values, and each measure can hence lead to a different ranking of datasets.

Proportional Species Turnover

To obtain Whittaker's species turnover, absolute species turnover β_{At} is divided by the mean species count in the compositional units α_i . Equally well, β_{At} can be divided by the total species count in the dataset γ . Doing so leads to a new relative species turnover measure, *proportional species turnover* (Tuomisto, 2010a)

$$\beta_{\text{Pt}} = (\gamma - \alpha_i) / \gamma = 1 - \alpha_i / \gamma \quad [24]$$

When the interest is in presence-absence data, proportional actual species turnover can be expressed more explicitly as

$$R'_{\text{p}} = (R_{\text{tot}} - R_{\text{mean}}) / R_{\text{tot}} = 1 - R_{\text{mean}} / R_{\text{tot}} \quad [25]$$

The prime is added to specify that this is a relativized measure of richness; that is, one richness is expressed as a proportion of another richness, which yields a unitless value. Subscript "P" refers to proportion. When the interest is in abundance data, proportional effective species turnover can be expressed as

$${}^qD'_{\text{p}} = ({}^qD_{\text{tot}} - {}^qD_{\text{mean}}) / {}^qD_{\text{tot}} = 1 - {}^qD_{\text{mean}} / {}^qD_{\text{tot}} \quad [26]$$

The proportional species turnover measures express what proportion of the species in the entire dataset is not contained in a single compositional unit (actual or effective). The term $R_{\text{mean}} / R_{\text{tot}}$ also indicates the proportion of subunits in which the average actual species occurs (mean species frequency; Whittaker, 1972; Routledge, 1977).

Proportional species turnover obtains its maximum and minimum values in the same situations as Whittaker's and absolute species turnovers do. Its minimum value is zero, and its maximum value is $1 - 1/N$ (for effective species turnover, the latter is true only if all nominal subunit weights are equal or $q = 1$). Just like Whittaker's species turnover, proportional species turnover is independent of how many species the dataset contains, and it can be used to compare the compositional heterogeneities of datasets that differ in the number of species. Proportional species turnover is monotonically (but curvilinearly) related with Whittaker's species turnover, so the two measures will always rank datasets in the same way (assuming, of course, that both are based either on richness data or on diversity data of the same order). Proportional species turnover has been derived several times (e.g., Roschewitz *et al.*, 2005; Ricotta, 2008; de Bello *et al.*, 2010). Unfortunately, it has usually been called beta diversity, even though it is both conceptually and numerically very different from true beta diversity (effective number of compositional units).

Resemblance Indices Related to Diversity

Several familiar similarity and dissimilarity indices can be derived as transformations of beta richness, beta diversity, or actual or effective species turnover in a dataset consisting of two subunits (Jost, 2006, 2007; Tuomisto, 2010a, b, c). For example, the Manhattan metric, as calculated using presence-absence data, is a simple transformation of absolute actual species turnover (Tuomisto, 2010a):

$$M = 2R_{\text{diff}} = 2(R_{\text{tot}} - R_{\text{mean}}) = b + c \quad [27]$$

Here b is the number of actual species unique to the first subunit and c is the number of actual species unique to the second. The Manhattan metric is not bound to any fixed interval, but can increase indefinitely as the number of species in the dataset increases. In some applications, this can be a desirable property, but in most situations where compositional resemblance indices are used, it is not. Therefore, in most cases it is more appropriate to use indices whose values are constrained to a fixed interval. Typically, compositional similarity indices take the value zero when the two subunits that are being compared share no species, and the value unity when both subunits have identical species compositions.

The Sørensen index equals the one-complement of Whittaker's actual species turnover (see Tuomisto, 2010a for derivation)

$$C_{\text{S}} = 1 - R'_{\text{W}} = 2 - R_{\text{tot}} / R_{\text{mean}} = 2a / (2a + b + c) \quad [28]$$

Here a is the number of species found in both subunits, and b and c the numbers of species found in one or the other subunit but not both subunits. The Sørensen index expresses the number of shared species as a proportion of the average number of species in the two subunits $R_{\text{mean}} = (2a + b + c) / 2$.

The Sørensen index can easily be expanded to abundance data by replacing actual species turnover with effective species turnover:

$${}^qC_{\text{S}} = 1 - {}^qD'_{\text{W}} = 2 - {}^qD_{\text{tot}} / {}^qD_{\text{mean}} \quad [29]$$

The addition of superscript q specifies that the calculations are based on diversity of order q . The classical (richness-based) Sørensen index is invariably constrained to the interval $[0, 1]$, which is often a desirable property in a similarity index. With the diversity-based Sørensen index, the minimum value is fixed at zero only when the maximum value of ${}^qD'_{\text{W}}$ is fixed at unity, which happens when both subunits have the same nominal weight or $q = 1$. Using ${}^qC_{\text{S}}$ as a similarity index therefore needs to be done with care to avoid misinterpreting the results. If different subunits have different total abundances, and it is for some reason not justified or desirable to rarefy them to the same number of individuals or convert them to within-subunit percentages, then only $q = 1$ should be used when correct interpretation of the results depends on ${}^qC_{\text{S}}$ being restricted to the interval $[0, 1]$.

The Jaccard index equals

$$C_{\text{J}} = 1 - 2R'_{\text{p}} = 2R_{\text{mean}} / R_{\text{tot}} - 1 = a / (a + b + c) \quad [30]$$

The Jaccard index expresses the number of shared species as a proportion of the total number of species in the two subunits $R_{\text{tot}} = a + b + c$. Just as with the Sørensen index, the

Jaccard index can be adapted to abundance data:

$${}^qC_J = 1 - 2^q D'_p = 2^q D_{\text{mean}} / {}^qD_{\text{tot}} - 1 \quad [31]$$

As with the diversity-based Sørensen index, the values of the diversity-based Jaccard index lie in the exact interval $[0, 1]$ only if both subunits contain the same abundance or $q=1$.

Since both richness and diversity can be calculated for any dataset, irrespective of the number of subunits it contains, both the Sørensen index and the Jaccard index can be generalized to more than two subunits. The Jaccard index equals the one-complement of proportional species turnover between two subunits as ranged to the interval $[0, 1]$ (obtained by dividing with the maximum value). Its values therefore naturally stay in this range even when $N > 2$. The multiple-site Jaccard index for presence-absence data can be written as (Tuomisto, 2010a)

$$C_{JN} = 1 - \frac{R'_p}{1 - 1/N} = \frac{R_{\text{mean}}/R_{\text{tot}} - 1/N}{1 - 1/N} \quad [32]$$

When $N=2$, the Sørensen index equals the one-complement of Whittaker's species turnover, but the value of the latter can exceed unity when $N > 2$, so ranging is needed to keep its value within the interval $[0, 1]$. The multiple-site Sørensen index for presence-absence data then becomes (Diserud and Ødegaard, 2007; Tuomisto, 2010a)

$$C_{SN} = 1 - \frac{R'_W}{N-1} = \frac{N - R_{\text{tot}}/R_{\text{mean}}}{N-1} \quad [33]$$

The one-complements of both C_{JN} and C_{SN} quantify how much the actual species turnover of the corresponding kind exceeds its minimum possible value, expressed as a proportion of the total possible range of values (given N). The one-complement of C_{SN} was proposed by Harrison *et al.* (1992) under the name "beta-1" (although their original equation gives values in percentages rather than proportions).

For effective species turnover, the maximum values are definable in terms of N only when all nominal subunit weights are equal or $q=1$, and ranging is therefore possible only when at least one of these conditions holds. Then the multiple-site Sørensen index for abundance data is (Tuomisto, 2010a)

$${}^qC_{SN} = 1 - \frac{{}^qD'_W}{N-1} = \frac{N - {}^qD_{\text{tot}}/{}^qD_{\text{mean}}}{N-1} \quad [34]$$

Similarly, the multiple-site Jaccard index for abundance data is (Jost, 2006; Tuomisto, 2010a)

$${}^qC_{JN} = 1 - \frac{{}^qD'_p}{1 - 1/N} = \frac{{}^qD_{\text{mean}}/{}^qD_{\text{tot}} - 1/N}{1 - 1/N} \quad [35]$$

The one-complements of both indices quantify how much the effective species turnover of the corresponding kind exceeds its minimum possible value, expressed as a proportion of the total possible range of values (given N).

Binary measures can be generalized to abundance data in different ways, and a particular nonlinear (but monotonic) transformation of diversity gives the following overlap index

(Chao *et al.*, 2008):

$$C_{qN} = \frac{({}^qD_{\text{mean}}/{}^qD_{\text{tot}})^{q-1} - (1/N)^{q-1}}{1 - (1/N)^{q-1}} \quad [36]$$

For $q < 1$, the exponents become negative and hence cause all terms to be inverted. How this affects the calculation can be seen by rewriting the equation in the mathematically equivalent form that has positive exponents when $q < 1$:

$$C_{qN} = \frac{N^{1-q} - ({}^qD_{\text{tot}}/{}^qD_{\text{mean}})^{1-q}}{N^{1-q} - 1} \quad [37]$$

Note that the parameter q in C_{qN} is specified in a subscript rather than in a superscript. This distinction is important, because even though C_{qN} is expressed as a function of true diversities of order q , it is not linearly related with qD but with the basic sum ${}^qD^{1-q}$ (see the explanation in connection with eqn [6]). The C_{qN} index is therefore a measure of compositional overlap (Chao *et al.*, 2008), not of relative species turnover as ${}^qC_{SN}$ and ${}^qC_{JN}$ are. As a result, C_{qN} behaves in a different way than ${}^qC_{SN}$ and ${}^qC_{JN}$ do when the value of q is changed.

In the special case of $q=0$, the C_{qN} index converges on the ${}^qC_{SN}$ index (compare eqns [37] and [34]), and both thus converge on the classical Sørensen index when $N=2$ (see eqns [29] and [28]). In the special case of $q=2$, the C_{qN} index converges on the ${}^qC_{JN}$ index instead (compare eqns [36] and [35]), and both converge on the Morisita-Horn index when $N=2$. The Morisita-Horn index generalized to N subunits can be written as (see Jost, 2006 for derivation)

$$C_{2N} = \frac{{}^2D_{\text{mean}}/{}^2D_{\text{tot}} - 1/N}{1 - 1/N} \quad [38]$$

In the special case of $q=1$ and $N=2$, the C_{qN} index converges on the Horn index (Chao *et al.*, 2008). The Horn index generalized to N subunits can be written as (see Tuomisto, 2010a for derivation)

$$C_{1N} = \frac{\log(N) - \log({}^1D_{\text{tot}}/{}^1D_{\text{mean}})}{\log(N)} \quad [39]$$

The C_{qN} index provides a valid and useful measure of overall compositional overlap among all sampling units in a dataset of interest at all values of q . At some values of q , it can also be interpreted in terms of effective species turnover. At $q=0$, C_{qN} equals Whittaker's species turnover expressed as a proportion of the maximum value obtainable, given N . At $q=2$, C_{qN} equals proportional species turnover expressed on a relative scale between the minimum and the maximum possible, given N . However, C_{qN} is not primarily a species turnover measure, and at other values of q , interpreting the value of C_{qN} in terms of species turnover is misleading. For example, at $q=1$, C_{qN} quantifies the magnitude of relative Shannon entropy, not relative species turnover. Conversely, the value of ${}^qC_{SN}$ can be interpreted in terms of relative Whittaker's species turnover at any value of q , but in terms of compositional overlap, only at $q=0$; the value of ${}^qC_{JN}$ can be interpreted in terms of relative proportional species turnover at any value of q , but in terms of compositional overlap only at $q=2$.

To choose an appropriate index for a particular study, it is necessary to understand which aspect of the data each index quantifies. Ecological hypotheses invariably concern some

specific aspect of data behavior, and choosing an index that corresponds to the wrong aspect can therefore lead to incorrect interpretations of the results and unjustified conclusions on the tested hypotheses. The mathematical properties of the indices also determine what needs to be taken into account when comparing their values among datasets, and indeed whether the index values can be meaningfully compared at all. How an index is calculated is not a mere technical detail, because it defines the variable of interest and hence the ecological meaning of the results obtained.

Glossary

Acclimation Processes by which plants adapt to changes in environment over time scales of days to weeks and longer.

Aerosol A suspension of liquid droplets or solid particles in air.

Arrhenius equation The standard relationship between the rate of a chemical reaction and temperature.

Big leaf An approximation to calculate the total rate of photosynthesis by a vegetation canopy, which is formally equivalent to treating the whole canopy as a single leaf.

Biome A broad vegetation type characterized by the dominance of one or more particular PFTs and with a particular structure and appearance, for example, boreal evergreen forest, savanna, desert.

Breathing of the biosphere The land takes up CO₂ during spring and summer, when photosynthesis exceeds respiration, and gives out CO₂ during autumn and winter, when the converse is true. This seasonal signal appears in atmospheric CO₂ measurements. The largest signal globally is from the mid- to high latitudes of the Northern Hemisphere.

CAM Crassulacean acid metabolism, a specialized photosynthetic pathway adopted especially by some desert plants, in which stomata close during the daytime (restricting water loss) and open during the nighttime allowing CO₂ to be fixed by PEP carboxylase (see C₄ plants).

Carbon cycle The circulation of carbon between atmospheric carbon dioxide and other inorganic and organic forms of carbon on land and in the ocean.

CASA The Carnegie-Ames-Stanford Approach model.

CTEM The Canadian Terrestrial Ecosystem Model, which is the land-surface component embedded in the Canadian Climate Model.

C3 plants Plants with the common photosynthetic pathway, including almost all trees and almost all plants of cool climates.

C4 plants Plants with a preliminary CO₂ concentration mechanism involving the enzyme phosphoenolpyruvate carboxylase (PEP carboxylase). Many C₄ plants achieve this with the help of a distinct leaf anatomy, although 'single cell' C₄ photosynthesis is known and may be evolutionarily ancient.

Cenozoic The past 65.5 million years, characterized by cooling and falling CO₂ concentrations.

Chilling A period with temperatures below about 5 °C, required by many temperate plants before they will respond quickly to spring warming.

CLM The Community Land Model of the National Center for Atmospheric Research, USA.

CO₂ fertilization The enhancement of NPP by increased atmospheric concentrations of carbon dioxide.

Colimitation The situation where the rate of supply of two or more essential resources are in balance, so that neither is in excess or deficit. Colimitation is economically optimal in situations where the rates of supply depend on investment.

Complexity (in models) A complex model is one that represents many different processes. Although there has been a tendency for models, including DGVMs, to become more and more complex, there are well-recognized problems with this, especially if the number of parameters increases. A rapidly growing school of thought in biology favors the use of models that are just complex enough for their purpose.

Cretaceous An epoch within the Mesozoic from 145.5 to 65.5 million years ago, characterized by the diversification of angiosperms.

CTEM The Canadian Terrestrial Ecosystem Model, which is coupled to the climate model of the Canadian Centre for Climate Modeling and Analysis.

Decomposition The breakdown of litter and soil organic matter by microbial respiration, leading to the release of carbon dioxide and inorganic forms of reactive nitrogen. In the global carbon cycle, NPP and decomposition are approximately balanced. The small difference is the net biosphere uptake (or release) of carbon.

DGVM Dynamic Global Vegetation Model.

Diffuse radiation Solar radiation from the sky or clouds, which is approximately the same in all directions. Diffuse radiation penetrates dense vegetation canopies more effectively than direct radiation.

Direct radiation Solar radiation from the solar beam, coming from one direction.

Disturbance Removal of biomass, for example, by fire, grazing or extreme winds.

D–O events Dansgaard–Oeschger events, large and rapid climate warming events that took place during the ice ages. The origins of D–O events are not fully established, but their effects are manifest around the world: they are strongest in the North Atlantic and surrounding land regions but also detectable in the tropics and southern hemisphere. The response of vegetation to D–O events is recorded by pollen analysis.

Down-regulation Acclimation that involves a reduction in the maximum rate of a physiological process.

Eccentricity The deviation of the Earth's orbit from circular. Eccentricity varies with periods around 100 thousand years, 400 thousand years and 1 and 2.4 million years.

Eocene A warm epoch within the Cenozoic, from 55.8 to 33.9 million years ago.

ESM Earth System model.

Evapotranspiration The sum of transpiration and evaporation from leaves and bare ground.

FACE Free air carbon dioxide enrichment, a computer-controlled system by which carbon dioxide is pumped into an experimental vegetation plot – taking account of varying wind speeds and direction – in such a way as to maintain elevated CO₂ concentration in the air above the plot. FACE gives clearer results than techniques involving chambers, because it eliminates the effect of enclosing the plants in chambers.

fAPAR Fraction of absorbed photosynthetically active radiation: that is, the fraction of solar radiation in the ‘photosynthetically active’ range of wavelengths that is absorbed by plants. fAPAR is measured from space and provides information about the ‘greenness’ of vegetation, which is related to total photosynthesis.

GPP Gross primary production, the rate at which CO₂ is incorporated into organic compounds by photosynthesis.

Holocene The past 11,700 years, corresponding to the present interglacial period of the Quaternary.

HYBRID A DGVM that incorporates an individual-based representation of vegetation dynamics, developed by Andrew Friend at various locations.

IBIS The Integrated Biosphere Simulator DGVM, developed at the University of Wisconsin-Madison.

Insolation Incoming solar radiation at the top of the atmosphere.

IPCC The Intergovernmental Panel on Climate Change, a United Nations body which conducts periodic comprehensive assessments of the science of climate change and its implications, with the involvement of a large number of scientists from all over the world.

JULES The Joint UK Land Ecosystem Simulator, a community land-surface model embedded in the Met Office Hadley Centre climate model.

Leaf economics spectrum The tendency of plant leaves to fall along a continuum of variation from thin leaves with fast turnover to thick leaves with slow turnover.

LGM Last glacial maximum, around 21 thousand years ago.

Liebig’s law (or the ‘law of the minimum’) The incorrect hypothesis that growth is always limited by the rate of supply of a single, ‘most limiting’ resource.

LPJ The Lund–Potsdam Jena DGVM.

LPJmL The ‘managed Land’ LPJ DGVM, developed at the Potsdam Institute for Climate Impacts Research, which includes process-based representations of crops and grazing lands.

LPJ-GUESS The LPJ-GeneriC EcoSystem Simulator, a variant of LPJ with more explicit vegetation dynamics, developed at Lund University.

LPX The Land-surface Processes and eXchanges DGVM, a variant of LPJ with a process-based fire model, developed by Colin Prentice’s team at various locations.

LSM Land-surface model (a component of a climate model).

MC1 The MAPPS/CENTURY 1 DGVM, developed at the US Forest Service. MAPPS is a previously developed biogeography model and CENTURY is a widely used biogeochemistry model.

Megafauna Large animals.

Mesic Environments with moderate to adequate water supply.

Mesozoic The period from 251 to 65.5 million years ago.

Mid-Holocene Around 6 thousand years ago, characterized by higher than present insolation in northern summer, warmer conditions than present in northern latitudes, and expanded northern hemisphere monsoons.

Miocene An epoch within the Cenozoic, from 23 to 5.3 million years ago.

Nitrogen cycle The circulation of nitrogen between atmospheric nitrogen gas and reactive inorganic and organic forms of carbon on land and in the ocean. The nitrogen cycle and carbon cycle are linked because of stoichiometric requirements, i.e., tissues of organisms have to have at least a certain proportion of nitrogen (the most abundant element after carbon, hydrogen and oxygen) relative to carbon in order to function.

Nitrogen deposition The deposition of reactive nitrogen that has been generated elsewhere, for example, in combustion, after atmospheric transport.

Nitrogen fixation The conversion of atmospheric nitrogen gas into reactive forms that can be used by organisms. The largest natural nitrogen fixation process is biological fixation, carried out by bacteria. Some nitrogen is fixed during lightning. The Haber–Bosch process (used in the industrial production of nitrogen fertilizer) is an additional major source of reactive nitrogen.

NDVI Normalized difference vegetation index, a simple remotely sensed measure related to fAPAR. Remotely sensed NDVI data are available from the early 1980s onward.

NPP Net primary production, the rate of production of new plant material. NPP is equivalent to the rate of GPP minus the rate of plant respiration, which is returned to the atmosphere as carbon dioxide.

Obliquity The tilt of the Earth’s axis, which influences total annual insolation at different latitudes. Obliquity varies on an approximately 40 thousand year cycle.

Oligocene An epoch during the Cenozoic, from 33.9 to 23.0 million years ago.

Optimality The idea that natural selection has eliminated all but the most effective modes of behavior by organisms that can be achieved given the biochemical and biophysical constraints. Optimality is a powerful generator of testable hypotheses for modeling biological systems.

ORCHIDEE ORganizing Carbon and Hydrology In Dynamic Ecosystems, the land-surface model embedded in the French (Institut Pierre Simon Laplace) climate and Earth System model.

Parameter A prescribed quantity in a model that does not have a precisely known or measurable value.

Perihelion The time of year when the Earth is closest to the Sun, which is currently in early January.

PFT Plant functional type. A group of plants assumed to have similar properties and responses to environmental changes.

ppm Parts per million, used to express molar mixing ratios of gases in the atmosphere.

Phenology The timing of seasonal events in the life of plants, such as spring budburst in climates with cold winters.

Photoperiod The length of the daylight period. Photoperiod is sensed by green tissues, and is involved in phenological events such as leaf abscission in autumn.

Plant functional traits Directly observable or measurable properties of plants that are related to how they work.

Pliocene An epoch within the Cenozoic, the most recent prior to the Quaternary, from 5.3 to 2.6 million years ago. The Pliocene is characterized by largely modern flora and fauna, and is the most recent epoch to have experienced extended periods globally warmer than present.

Precession The drift of the timing of perihelion through the year, which influences the distribution of insolation with season and latitude. Precession has two major periods of 19 and 23 thousand years.

Quaternary The past 2.6 million years. The Quaternary has been characterized by the alternation of ice ages and interglacials with fluctuating, low CO₂ concentrations that were lowest during peak ice-age conditions and highest during interglacial conditions (warm periods).

Recycling (of water) Transpiration and evaporation from the land surface followed by reprecipitation elsewhere within the continent.

Resprouting Refers to woody plants that are not killed by fires, but sprout new leaves, either from the base or from epicormic shoots (new shoots originating beneath the bark).

Rubisco (or RuBisCO) Ribulose-1,5-bisphosphate carboxylase oxygenase, the central enzyme of photosynthesis. *Rubisco capacity* is the maximum rate of carboxylation (incorporation of carbon dioxide into carbohydrates), determined principally by the amount of Rubisco and other proteins needed for photosynthesis. Because maintenance of these proteins is expensive, the Rubisco capacity is actively regulated by the plant.

Runoff Water that is left over after evapotranspiration. Runoff is the source of freshwater in streams and rivers.

SDGVM The Sheffield DGVM, developed at the University of Sheffield.

Seeding Refers to plants whose seeds germinate abundantly after fires, thus quickly re-establishing a population from seeds.

Soil moisture deficit The difference between the water content of soil and the water content of the same soil at field capacity, i.e., after saturation followed by drainage.

Stoichiometry The ratios of different elements in a material. For example, a plant tissue requires not only carbon, but also nitrogen, phosphorus, and other elements in certain 'stoichiometric' proportions.

Stomatal conductance The conductance for water vapor or carbon dioxide across the leaf surface, which depends on the degree to which the stomates are open or closed. Conductance is the inverse of resistance, so the rate of exchange of carbon dioxide across the leaf surface is equal to the product of stomatal conductance and the difference in the concentration of carbon dioxide outside and inside the leaf.

Stomates (or stomata) Pores in the leaf surface, surrounded by guard cells that regulate the openness of the pores.

Trace gases Gases present in the atmosphere in low mixing ratios (typically less than a few ppm). Some trace gases, including methane, nitrous oxide, and ozone, are greenhouse gases. Others are reactive in the atmosphere and influence the greenhouse effect indirectly. For example, carbon monoxide – produced in fires – competes with methane for the available oxidizing capacity of the atmosphere, and so an increase in carbon monoxide emission leads indirectly to a higher methane concentration.

Transpiration The process by which vascular plants take up water through the roots, transport it through the xylem, and evaporate it from the surface of the leaves.

TRY The global data base of plant functional traits, maintained by the Max Planck Institute for Biogeochemistry in Jena, Germany and governed by an international steering committee.

Vapor pressure deficit The difference between the water vapor content of the air and the saturated water vapor content of the air at its current temperature, the driving force of transpiration.

VOC Volatile organic compound. Many VOCs are emitted by plant leaves, of which the most abundant is the unsaturated hydrocarbon isoprene. VOCs have many functions in plants, including protection against heat stress damage and damage by insect herbivores.

Wetland A terrestrial ecosystem with a water table that is permanently close to the surface.

Xeric Environments with low water supply.

Xylem Water-conducting tissue in the stem or transport roots of vascular plants.

Article Outline

This article is a critical reflection on a class of numerical models that represents large-scale processes in the terrestrial biosphere. DGVMs serve multiple functions. They provide a means of systematizing knowledge about plants and ecosystems that is functional rather than descriptive, and universal rather than particular to a biome or region. DGVM development has stimulated additional research revealing general, empirical relationships among plant functional traits,

and between traits and environment. DGVMs also allow predictions of the impacts of climate change on ecosystems, and biogeochemical feedbacks to climate change. But despite impressive achievements in modeling emergent phenomena, such as the 'breathing of the biosphere', predictions of climate change impacts and feedbacks are still highly uncertain, varying greatly among models. The authors argue that the tools and datasets are at hand to reduce such uncertainties. The authors pay particular attention to the role that can be played by modeling the nature and function of past

ecosystems, including those in 'deep time' when the dominant plants were functionally different from today's, as well as those in more recent geological history. The latter provide case studies for the responses of the modern biota to a range of environmental changes, including large and rapid climate changes. The former should provide fundamental insights on Earth system evolution.

Why make Global Models of Ecosystems?

During the summers of 1988 and 1989, Allen M. (Al) Solomon invited a group of scientists to engage in extended brainstorming and collaboration at the International Institute for Applied Systems Analysis in Laxenburg, near Vienna. His agenda was deceptively simple. It was to start development of a new class of multifunctional models, which would seamlessly represent the multiple processes involved in predicting how ecosystem structure and function respond to global environmental change. For many participants, Al's initiative re-set their research priorities for the next decade. Dynamic Global Vegetation Models were the outcome.

The idea of DGVMs was taken up by the Global Change and Terrestrial Ecosystems project of the International Geosphere-Biosphere Programme, which announced an intercomparison project for DGVMs before any had actually been constructed. The ensuing scramble to make a working model eventually led to the much-cited article by Cramer *et al.* (2001), who presented historical simulations and future projections with DGVMs that had been developed by six independent groups.

By that time, several climate modeling groups had seen the potential of DGVMs to provide an interactive lower boundary for the atmosphere, and a dynamically changing carbon cycle in which the carbon balance of ecosystems would feed back on the atmospheric concentration of carbon dioxide. After groundbreaking publications on this new field of 'coupled climate-carbon cycle modeling' by Cox *et al.* (2000) and Friedlingstein *et al.* (2001), applications of DGVMs to carbon cycle questions took center stage. Indeed, Cramer *et al.* (2001) already focused on the carbon cycle implications of projected future changes in CO₂ uptake by ecosystems, including both negative and positive feedbacks due to CO₂ fertilization and accelerated decomposition, respectively. The paper's findings on the role of terrestrial ecosystems in the carbon cycle were showcased in the Third Assessment Report of the Intergovernmental Panel on Climate Change (Prentice *et al.*, 2001). Carbon cycle applications have dominated the DGVM literature ever since.

Several other applications of DGVMs were envisaged from the outset and remain important goals. These include predictions of how different aspects of the terrestrial biosphere, such as vegetation structure and habitats, river flows (an indirect consequence of water use by vegetation), and trace gas emissions, respond to environmental change, and how the terrestrial biosphere has influenced and been influenced by climatic and environmental changes in the geological past. These fields of application are summarized later in this article.

More fundamentally, behind the development of DGVMs lay a more radical, unwritten agenda: to realign ecology's

research priorities with the requirements of global change research. In the late 1980s, ecology almost completely lacked a focus on (or funding for) either the study of global-scale phenomena, such as the relation between vegetation structure and macroclimate (then often derided for being nonexperimental science), or even more crucially, a search for empirical generalizations that would apply globally, across different biomes and regions. The prevailing wisdom at the time held that models should be developed (if at all!) for one biome at a time, emphasizing processes important in a particular biome – neglecting the difficulty that climate change was already known (from paleoecology) to be capable of converting one biome into another, so without a generic model, there would be no way to predict the dynamics of such transitions. The development of DGVMs has made this position untenable, and has helped to establish 'global ecology' or 'macroecology' as a high-profile area of science.

Comparative information on plant traits across species and biomes was scarce at that time, and modelers were obliged to rely on a very limited information base dominated by a few species of commercial importance. This situation too has changed drastically. The past decade has seen the emergence of important generalizations based on quantitative trait data from thousands of species, such as the leaf economics spectrum (Wright *et al.*, 2004), while TRY data base has brought together more than 2 million pieces of quantitative and qualitative information on over 70,000 species of vascular plants (Kattge *et al.*, 2011). This effort has been stimulated, and frequently justified to funding agencies, precisely by the need to provide better information for DGVMs.

This article is a critical reflection on the state of DGVMs. The authors suggest that they have only partially fulfilled their original promise, while providing a number of pointers to how their usefulness could be enhanced; not least, by taking on board the implications of the 'data revolution' alluded to above. The reader is also referred to Arora (2002), Woodward and Lomas (2004), Prentice *et al.* (2007), and Tang and Bartlein (2008). The authors note that applications to questions of biophysics (land-atmosphere interactions) and biogeochemistry (carbon and to a lesser extent nitrogen cycling) have tended to dominate over applications to questions of community composition and biodiversity. Yet the framework of DGVMs would allow far more to be done in terms of predicting climate change impacts on habitats and species, while the newly data-rich world of plant functional ecology should allow greater realism and reliability to be achieved in models.

Types of Ecosystem Model and their Relation to DGVMs

The building blocks of DGVMs and how they were fitted together have been reviewed by Prentice *et al.* (2007). Briefly, DGVMs represent a merger of four previously distinct modeling strands, developed by separate research communities, *biogeography* models originated from vegetation-oriented climate classifications such as that of Köppen (1918). Biogeography models predict the broad-scale distribution of biomes, assumed to be static and in equilibrium with climate. Woodward (1987) and Prentice *et al.* (1992) showed how a combination of independent limiting

values of bioclimatic variables (indices of winter cold, summer warmth, and moisture availability) could predict biome distributions in the different continents with surprising realism, thus injecting a more explicit process basis into biogeography modeling. *Vegetation dynamics* models emerged from regionally specific, individual-based models that predicted forest succession patterns from basic allometric and growth traits of trees (Botkin *et al.*, 1972; Shugart, 1984). Although these models in general did not preserve mass or energy balance, they were a step forward from earlier attempts to model vegetation dynamics purely from observed transitions between discrete vegetation states. *Biogeochemistry models* (e.g., Running and Coughlan, 1988; Running and Hunt, 1993; Raich *et al.*, 1991; Melillo *et al.*, 1993; Parton *et al.*, 1993; Del Grosso *et al.*, 2001) by contrast focused on mass balance as opposed to vegetation structure and composition, and described the coupled cycling of carbon, water, and (usually) nitrogen through ecosystems of a given type on multiannual time scales. *Soil-vegetation-atmosphere models* focused on fast cycling processes (carbon uptake and release, evapotranspiration, and water balance, usually with subdaily time steps), assuming the structure of the ecosystem and the masses of different plant compartments to be fixed. This last category of models also provided the foundations for *land-surface models*, built into atmospheric general circulation models (climate models) (Seller *et al.*, 1997). In DGVMs, the different levels of process represented by the four model categories are linked through partially synchronous coupling so that (for example) plant water and carbon balances are updated at daily or subdaily time steps whereas vegetation dynamics is modeled on annual time steps (Prentice *et al.*, 2007).

These modeling strands have continued to develop independently or in various combinations. For example, some contemporary models for vegetation dynamics use explicit approximations to allow the modeling of individual-based competition without actually simulating individuals (e.g., Medvigy *et al.*, 2009). Models for biogeography, appropriate to the representation of 'snapshots' of paleoecological time, now incorporate elements of biogeochemistry modeling so as to allow the representation of competitive interactions between trees and grasses, evergreen versus deciduous trees, C_4 versus C_3 herbaceous plants, and effects of changes in atmospheric CO_2 concentration on these interactions (Haxeltine and Prentice, 1996a). But DGVMs are a well-established line of development in their own right, and in principle they can be used for all the purposes suitable to their constituent submodels.

DGVMs also form a component of *coupled climate-carbon cycle models* (Cox *et al.*, 2000; Friedlingstein *et al.*, 2001, 2006), and of comprehensive *Earth system models*. Comprehensive ESMs aim to include a range of land-atmosphere and ocean-atmosphere interactions in a fully coupled manner, for example, trace gas emissions from ecosystems, which affect atmospheric composition, which in turn affects climate and ecosystems (Scholze *et al.*, 2012). The first generation of ESMs has been developed and run by climate modeling groups for the Fifth Assessment Report of the IPCC, for publication in 2013–2014. At the time of writing, these ESMs are in an early stage of development. Nevertheless, there are good reasons to aspire to coupled modeling of the biological, physical, and chemical aspects of the global environment. DGVMs now form an indispensable part of the Earth system modeling toolkit.

There are now many more DGVMs than the original six compared in Cramer *et al.* (2001). Some of the more extensively used and developed DGVMs include CASA (Potter *et al.*, 1993; deFries *et al.*, 1999), CLM (Levis *et al.*, 2004), CTEM (Arora and Boer, 2006; Christian *et al.*, 2010), HYBRID (Friend and White, 2000; Friend and Kiang, 2005; Friend, 2010), IBIS (Foley *et al.*, 1996; Kucharik *et al.*, 2000), JULES (Alton *et al.*, 2007; Clark *et al.*, 2011), LPJ and LPJmL (Sitch *et al.*, 2003; Gerten *et al.*, 2004; Bondeau *et al.*, 2007), LPJ-GUESS (Smith *et al.*, 2001), LPX (Prentice *et al.*, 2011a), MC1 (Lenihan *et al.*, 1998), ORCHIDEE (Krinner *et al.*, 2005), and SDGVM (Woodward *et al.*, 1998; Woodward and Lomas, 2004). This is not a comprehensive list. New models are being developed all the time for either coupled or stand-alone applications or both. Sitch *et al.* (2008) presented an intercomparison of five DGVMs. Murray *et al.* (2012) provide a longer list of DGVMs that have been used in hydrological applications.

Principles and Processes in DGVMs

From Empirical to Process-Based Modeling: A Well-Traveled (But Bumpy) Road

The representation of fundamental leaf-level processes in DGVMs and their precursor models evolved from early attempts based on empirical dependencies of plant growth on climate variables (solar radiation, temperature, and precipitation) toward more explicitly process-based representations, which generally have superior power to predict the behavior of plants in changing biotic and abiotic environments. Plant growth, for example, is now usually quantified in DGVMs as a balance of photosynthesis, predicted either using the standard model of Farquhar *et al.* (1980) or a common simplification thereof, and respiration associated with the growth and maintenance of different tissues. The Farquhar model includes a number of coefficients that are almost constant among different plants at any given temperature, and with a known temperature dependence (e.g., the affinities of Rubisco for CO_2 and oxygen). The model describes photosynthesis by C_3 plants but it has been modified to apply to C_4 plants as well. The rationale of applying such a general model is that a few basic characteristics (e.g., photosynthetic pathway) and measurements (e.g., Rubisco capacity) on plants then provide enough information to predict photosynthesis under a vast range of environmental conditions.

But there are still difficulties, because Farquhar's model does not tell us, for example, how one might expect Rubisco capacity to vary seasonally or between different climates. Many DGVMs simply apply a constant value for each type of plant, but this approach ignores acclimation processes. Similarly, plant respiration in most DGVMs is assumed to vary with temperature following the Arrhenius equation, which is well-established for short-term measurements, or a simple exponential relationship, which is an adequate approximation to the Arrhenius equation over a moderate range of temperatures. But recent research has shown that plant respiration acclimates to temperature so as to almost entirely negate this temperature dependence on time scales of weeks or longer, i.e., the main time scales at which we would like to apply

DGVMs (Atkin and Tjoelker, 2003; Atkin *et al.*, 2008; Zaragoza-Castells *et al.*, 2008). Most current DGVMs do not allow for this acclimation and therefore must produce incorrect longer term responses of plant respiration to temperature. Some models however have assumed that plant respiration constitutes a fixed fraction of photosynthesis; this may be oversimplified, but at least it is consistent with the evidence for respiratory acclimation (Gifford, 2003).

Adoption of process-based models is not a panacea. The way in which models represent the longer term acclimation of basic physiological processes as discussed in the previous paragraph is just one area where even DGVMs that appear to use the same, well-tested process model can get very different (and potentially wrong) results. The following subsections provide a (nonexhaustive) list of key processes for which many different approximations are in use, some better justified than others, and where more critical evaluation and comparison with observations would be desirable.

Carbon–Water Coupling

A basic tenet of ecophysiology, made explicit in DGVMs, is that plants lose water during transpiration when stomata open to take up CO₂ from the atmosphere during photosynthesis. Thus, there is a close coupling between carbon gain and water loss, both being regulated by stomatal ‘openness.’ There is no established mechanistic model for stomatal behavior. But there is a powerful and well-supported theory (Cowan and Farquhar, 1977), based on the idea that stomata behave in such a way as to optimize the marginal carbon gain per unit water loss (see also Schymanski *et al.*, 2009). Some DGVMs explicitly simulate stomatal conductance (the measure of stomatal openness) based on some variant of this principle (e.g., Friend, 1991). Others use long-standing empirical formulations, such as the Ball–Berry model (Ball *et al.*, 1987) which relates stomatal conductance to photosynthetic rate, ambient CO₂ concentration, and relative humidity.

The analysis by Medlyn *et al.* (2011) has shown that the difference between the Ball–Berry formulation and the optimization approach, mathematically speaking, is slight. Both lead to a strong inverse dependence of stomatal conductance on atmospheric vapor pressure deficit (dryness). But important open questions remain to afflict the modeling of plant responses to drought. For example, the Cowan–Farquhar theory relies on an ‘exchange rate’ between water and carbon, which is expected to vary among plant types, and with soil moisture. Much less is known about these variations than about the rapid response of stomatal conductance to atmospheric dryness. There is also evidence that photosynthetic rates decline with soil moisture more steeply than would be expected from the behavior of stomatal conductance alone. Some models incorporate an inhibition of photosynthesis by soil moisture deficit, others do not.

Responses to Atmospheric CO₂ Concentration

The short-term response of photosynthesis to increase the ambient concentration of CO₂ is well established. At present-

day ambient CO₂ or (especially) lower ambient CO₂, there is a positive response of photosynthesis in all C₃ plants. This response is predicted accurately by the Farquhar model, and is included in most DGVMs. In addition, stomata tend to close somewhat in response to increasing ambient CO₂. This behavior is consistent with the maintenance of a constant ratio of leaf-internal to ambient CO₂. Models that treat this ratio as conservative will predict it, others may not do so.

There is evidence from many plant species for an acclimation response of photosynthesis, such that Rubisco capacity declines with increasing CO₂ (Medlyn *et al.*, 1999). But the decline in Rubisco capacity is generally accompanied by an increase in photosynthesis. This behavior can be predicted from an optimality hypothesis formulated by Dewar (1996) and Haxeltine and Prentice (1996b), namely that Rubisco capacity optimizes the balance of photosynthesis and respiration at the leaf level, over a period of days to weeks. To the authors’ knowledge, only the Lund–Potsdam–Jena (LPJ) model (Sitch *et al.*, 2003) and its descendants include this criterion. Furthermore, the experimental literature commonly attributes this acclimation (or ‘down regulation’) to ‘dilution,’ nitrogen deficiency, or other limitations on growth. The jury is out.

In any case, most models assume Rubisco capacity to be fixed for a given type of plant. The particular consequences of allowing photosynthetic acclimation in a model have rarely been investigated. Arora *et al.* (2009) used the Canadian coupled climate–carbon cycle model to test the effect of photosynthetic acclimation over the period 1850–2000 AD. In simulations without photosynthetic acclimation, atmospheric CO₂ at 2000 was 15–20 ppm lower than observations. Inclusion of a realistic level of acclimation corrected this discrepancy. But it is not automatic that reducing carboxylation capacity would reduce CO₂ uptake. Too high a value would incur respiratory costs in excess of achievable gains.

Photosynthetic responses do not necessarily predict responses of plant growth. Growth may be constrained by low temperatures, and/or insufficient availability of essential nutrients to convert fixed carbon into plant tissues, whose stoichiometry can only vary within certain limits. Knowledge of the growth responses of field-grown plants and *in situ* ecosystems has increased greatly through the implementation over the past decade or so of free air carbon dioxide enrichment (FACE) experiments (Hendry *et al.*, 1993; Hendry and Kimball, 1994; Kimball *et al.*, 1995; Nowak *et al.*, 2004; Ainsworth and Long, 2005; Albert *et al.*, 2011; Norby and Zak, 2011). Norby *et al.* (2005) showed that a 200 ppm increase in ambient CO₂ concentration in forest FACE experiments induces an increase in NPP consistently close to 23% across a wide range of absolute NPP values. Hickler *et al.* (2008) showed that the LPJ-GUESS model produces approximately this level of NPP enhancement in temperate forests, but noted that the model also predicts much smaller enhancements in boreal forests and much larger enhancements in tropical forests, where as yet there are no FACE experiments to test the prediction. There is also considerable uncertainty about the sustainability of the growth response to CO₂, and the sources of the additional nitrogen that would be required to sustain such an increase (e.g., Finzi *et al.*, 2007; Norby *et al.*, 2010; Hofmockel *et al.*, 2011).

Carbon–nitrogen Coupling

The topic of CO₂ ‘fertilization’ of plant growth leads naturally to the consideration of nutrient limitations on growth. Hungate *et al.* (2003) criticized the predictions of future global land CO₂ uptake made by the DGVMs in Cramer *et al.* (2001), on the grounds that the models did not include limitations on growth due to limited nitrogen availability. In fact, two of the models (SDGVM and Hybrid) did include nitrogen limitations, and these two showed the smallest growth responses. But they still exceeded Hungate *et al.*’s (conservative) range of estimates for the maximum possible response.

The interactions of the terrestrial carbon and nitrogen cycles are not well understood. There is evidence for a reduction in the CO₂ fertilization effect on forest growth under more nitrogen-deficient conditions (e.g., Oren *et al.*, 2001; Dieleman *et al.*, 2010; Norby *et al.*, 2010). It is often asserted that nitrogen supply limits the response of plant growth to CO₂. However, plenty of counter-examples exist. Nowak *et al.* (2004) analyzed results from FACE experiments in a variety of ecosystems, including several where nitrogen status had been manipulated as well as CO₂. They found that there was often a very large response of growth to the combination of nitrogen addition and elevated CO₂. However, they were not able to show that the relative enhancement of growth by elevated CO₂ was different between plots with normal and increased nitrogen nutrition. Lee *et al.* (2011) showed a mean enhancement of NPP in grasslands by about 10% over a decade – less than some models would predict, but the enhancement was independent of the nitrogen status of the ecosystems.

The inclusion of interactive nitrogen cycling has recently become a major focus of DGVM development (Ostle *et al.*, 2009). Motivations include attempting to more realistically simulate the effects of increasing CO₂ on growth, the feedbacks from soil organic matter decomposition to climate, and the effects of anthropogenic nitrogen deposition on growth (e.g., Gu *et al.*, 2010). New models or versions of models with interactive carbon and nitrogen cycling have been presented by Thornton *et al.* (2007), Sokolov *et al.* (2008), Xu-Ri and Prentice (2008), Jain *et al.* (2009), Gerber *et al.* (2010), Zaehle and Friend (2010), Zaehle *et al.* (2010), and Esser *et al.* (2011). These models have yielded a startling diversity of results. There is unfortunately no consensus on how (and what) observations could be used to discriminate between different models. Results of field experiments may provide the most valuable benchmarks. Zaehle and Friend (2010), for example, showed how modeled responses to soil warming could be improved by the inclusion of an interactive nitrogen cycle.

Outstanding problems for modeling include the poorly constrained nature of estimates of total global nitrogen fixation, the ultimate source of most reactive nitrogen to ecosystems, and denitrification, the major pathway of gaseous nitrogen loss; failure to consider the recycling of nitrogen from sedimentary rocks, a previously overlooked natural nitrogen source (Morford *et al.*, 2011); and failure to consider the ways in which plants can allocate carbon in order to acquire nitrogen. This last consideration forms the basis for a promising new approach that seeks to optimize the marginal gain in growth (due to increased nitrogen acquisition) per unit of carbon invested, and allows plants to switch accordingly

between alternative pathways of nitrogen uptake (Fisher *et al.*, 2010).

Carbon Allocation and Multiple Resource Limitations

One important ecophysiological process resulting in major differences in DGVM simulations of carbon gain in plants is how fixed carbon is allocated between plant organs (leaves, woody tissues, and fine roots) (Malhi *et al.*, 2011). This too is relevant to the question of carbon–nitrogen cycle coupling, because all mechanisms that would increase the uptake of nitrogen from soils involve increased allocation below ground and therefore a trade-off between nutrient and light capture. Below-ground carbon allocation is important not only for its effects on nutrient acquisition and productivity, but also as a major carbon source for soil organic matter (Johnson *et al.*, 2011) and as a regulator of soil decomposition rates (Metcalfe *et al.*, 2011). There are abundant (albeit unsystematically collected) experimental data on plant allocation responses to a variety of environmental manipulations, forming the basis for the analysis by Poorter *et al.* (2012). This analysis provides a wealth of quantitative information, which should now be used to improve the representation of carbon allocation in DGVMs.

DGVMs have adopted various *ad hoc* representations of how different environmental constraints in combination control plant growth. Some seem to have been influenced by ‘Liebig’s law’, the hypothesis that growth is controlled by a single, ‘most limiting’ factor. This hypothesis is generally false for complex organisms such as higher plants – as shown, for example, by the fact that plants can show positive growth responses to increased supplies of water, nitrogen, and CO₂ in a single experiment. A general theoretical approach is much needed to replace this misleading hypothesis. The authors suggest that the key is recognizing that the acquisition of any resource depends on the allocation of carbon. So when a particular resource is in short supply, the optimal response may involve allocating more carbon to acquisition of that resource (e.g., Rastetter *et al.*, 2001; Rastetter, 2011). This principle is in direct contradiction to ‘Liebig’s law’, but it corresponds to a well-established tenet in microeconomics and has considerable predictive power for plants and ecosystems. For example, it predicts colimitation of photosynthesis by water and nitrogen (Wright *et al.*, 2003) and colimitation of plant growth by nitrogen and phosphorus, now recognized to be widespread (e.g., Domingues *et al.*, 2010; Harpole *et al.*, 2011).

Interactions specific to particular resources need to be considered as well, and can sometimes be counter intuitive. For example, it has been observed that nitrogen fertilization can lead to a large enough decrease in below-ground carbon allocation that trees’ drought resistance is impaired (e.g., Graciano *et al.*, 2005). The prevalence of symbiotic nitrogen fixation in tropical ecosystems, where phosphorus is often scarce, has been explained by the high nitrogen content of extracellular phosphatases that can help plants to acquire phosphorus from otherwise inaccessible chemical forms. This last suggestion forms part of the basis for the biogeochemical model of Wang *et al.* (2010b).

Scaling from Leaf to Canopy

DGVMs face the challenge of representing, in a simple but sufficient way, the properties of canopies that are almost intractably heterogeneous – both horizontally and vertically. The first and simplest approach involves a ‘big leaf’ (sometimes derogatorily called ‘green slime’) approximation. The ‘big leaf’ approximation has been justified mathematically on the grounds that it holds, in theory, when the vertical profiles of light availability and nitrogen content of foliage are similar (Sellers *et al.*, 1992; Friend, 2001). Both decline with depth in the canopy, but in reality the gradient of leaf nitrogen per unit area is less steep than the gradient of light attenuation (e.g., Lloyd *et al.*, 1995, 2010). It has also been shown that a ‘two big-leaf’ approximation, which divides the canopy into a sunlit and shaded fraction, is more exact (e.g., de Pury and Farquhar, 1999; Zeng *et al.*, 2003). The scaling of leaf-level processes to the canopy remains an active issue (Ren and Henderson-Sellers, 2006; Popp *et al.*, 2009; Chen *et al.*, 2011; Zhu *et al.*, 2011). Some DGVMs now include an explicit vertical profile of canopy properties (Mercado *et al.*, 2007), which facilitates modeling of some processes such as the different canopy penetration by diffuse and direct radiation, with implications for total canopy photosynthesis (Mercado *et al.*, 2009).

Plant Functional Types

The characterization of vegetation cover as being composed of a quantitative mixture of plant functional types, as opposed to classifying vegetation into qualitatively distinct biomes, was a major step forward for process-based biogeography modeling (Prentice *et al.*, 1992) and a prerequisite for dynamic modeling. The ecophysiological foundations for bioclimatic distinctions among PFTs have been reviewed by Harrison *et al.* (2010a). The PFT concept also applies to distinctions, for example, between early and late successional plants, or plants with different responses to fire or grazing pressure. There is an extensive literature on PFTs (e.g., Woodward and Cramer, 1996; Díaz and Cabido, 1997; Wright and Westoby, 2002; Wright *et al.*, 2005; Lavorel *et al.*, 2011; Fyllas *et al.*, 2012). The fundamental idea behind PFTs is that there are inevitable trade-offs between different plant traits, such that not all combinations of traits are possible; therefore, plants can be classified into a manageable number of PFTs. This idea also leads to the notion of a low-dimensional continuum of plant trait combinations (Wright *et al.*, 2004; Prentice *et al.*, 2011b). The evidence supports continuous variation for many plant traits, and also shows the coexistence of many different trait values within any given community.

Current DGVMs, which classify all plants into a small number of PFTs (typically between five and 15), therefore probably underestimate the ability of communities to adapt to environmental change through selection for species with different trait values within a model-defined PFT. They certainly underestimate the functional diversity of communities. It is likely that future DGVMs will include methods to better represent continuous trait variations within a limited number of discrete (or almost-discrete) classes, such as C_3 versus C_4 and CAM photosynthetic pathways; the tree habit versus the shrub,

forb, and graminoid habits; deciduous versus evergreen phenological types; and gymnosperm versus angiosperm wood anatomies.

Phenology

Phenology describes the seasonal timing of events in the life of an organism. In the DGVM context, the key phenological events that are modeled are the timing of budburst, the length of time required to the full ‘leaf-on’ state, and the timing of leaf senescence and/or abscission. Although these events take place in all green plants, most DGVMs consider them only for deciduous woody plants in seasonal climates, and perennial herbaceous plants with seasonal display of above-ground biomass. The key importance of modeling these particular cases lies in the control they exert on the seasonal pattern of ‘greenness’, i.e., the fraction of absorbed photosynthetically active radiation, which is a principal control on the rate of photosynthesis at the ecosystem level.

FAPAR is routinely measured by satellite instruments that record the relative reflectance of the ground surface in different spectral bands. The prototype of this measurement is the normalized difference vegetation index, which is based on a comparison of spectral reflectances in just two frequency bands: the red (where chlorophyll absorbs most strongly) and the near infrared, where chlorophyll does not absorb. The global NDVI record goes back to the early 1980s. Owing to the availability of satellite data, a subclass of DGVMs has emerged in which phenology and leaf area are not explicitly modeled, but instead prescribed from data (e.g., the CASA model, DeFries *et al.*, 1999). However, as phenology is highly responsive to climate, it is important for many purposes also to be able to predict phenology and leaf area (Arora and Boer, 2005a). Most DGVMs have this capability. It is best developed for high latitude climates with a short growing season, where ‘leaf-on’ can be predicted reliably with a simple growing degree day index (Harrison *et al.*, 2010a) and ‘leaf-off’ predicted, albeit less reliably, with a threshold temperature. Lucht *et al.* (2002) showed that the high latitude ‘greening’ (increasing leaf area and duration) trend observed in NDVI data by Myneni *et al.* (1997) could be reproduced using the LPJ model, as could the associated advancement of leaf-on in spring, and the temporary setback to both trends that was observed later after the eruption of Mount Pinatubo in 1991. However, phenology in other regions is more complex than in high latitudes. Woody plants have evolved mechanisms to prevent a too-rapid response to warm intervals in winter so that the accumulated warmth required for budburst depends inversely on the length of a preceding period of chilling (Murray *et al.*, 1989). Botta *et al.* (2000) combined NDVI and climate observations to fit different models for the phenology of different PFTs, including a chilling-dependent model for temperate trees. The resulting scheme has been included in the ORCHIDEE DGVM. But this is certainly not the last word. Experimental studies have shown a subtle interplay of photoperiodic and climatic responses (Chuine, 2000), which has yet to be incorporated in a DGVM.

The simulation of phenology in tropical biomes has caught researchers’ attention in part because simulations indicate that

some evergreen tropical rainforest may be replaced by more seasonal vegetation (seasonal forest or savanna) in a warmer world. But there is a dearth of experimental information on the phenology of tropical plants, compared with temperate and boreal regions (Bradley *et al.*, 2011). A preliminary study of the Amazon Basin yielded two distinct responses with solar radiation being the cue for phenology in upland (more mesic) forests, and precipitation being the regulator in savanna ecosystems.

Fire

Fire is the principal cause of vegetation 'disturbance' (removal of biomass) worldwide and endemic to all biomes except the wettest and the most sparse (driest or coldest) (Bowman *et al.*, 2009; Krawchuk *et al.*, 2009; Harrison *et al.*, 2010b). There is a vast literature on the modeling of fire at the landscape scale, but there have been relatively few attempts to model fire in a generic, global way. Nevertheless, several DGVMs do now include representations of fire. The basic principle of fire modeling is that it must be represented as a feedback process. Vegetation state (availability and dryness of fuels) controls the probability of burning and the rate, intensity, and duration of fire spread. Fire in turn, depending on its extent and properties, impacts the vegetation state by removing fuel, killing plants (or simply temporarily removing their leaves in the case of perennial herbaceous plants and 'resprouting' woody PFTs), and allowing the establishment of new plants in the case of 'seeding' PFTs.

The development of fire modeling during the early development of PFTs was handicapped by a lack of a consistent global historical dataset that could be used to test and refine models. This situation has now changed, with the advent of global remotely sensed data products (Giglio *et al.*, 2010; van der Werf *et al.*, 2010). At least two distinct strands of process-based, global fire modeling have emerged. One draws on the work of Rothermel (1972), who developed the first physically based approach to fire modeling in the context of operational fire management. Global modeling can use Rothermel's equations directly although it requires many quantities, which are measured in operational work, to be estimated somehow from the modeled vegetation properties and prescribed traits of PFTs. This approach was pioneered by the group of Ron Neilson at the US Department of Agriculture Forest Service (Lenihan *et al.*, 1998) and adopted by Thonicke *et al.* (2010) and Prentice *et al.* (2011a) in the LPJ family of models. An alternative, less complex process-based formulation, tailored more specifically to the requirements of DGVMs, was developed by Arora and Boer (2005b) for the CTEM.

It is likely that the representation of fire in DGVMs will evolve considerably during the coming years. One major complication needing to be tackled is the role of human activities. Although many human-set fires can be considered to 'pre-empt' fires that would otherwise have started naturally (especially in highly fire-prone ecosystems such as savannas), this is a great simplification of a complex reality. On the one hand, models that disregard human ignitions not surprisingly fail to reproduce 'deforestation fires' linked to El Niño events in Amazonia and southeast Asia. On the other hand,

contemporary human land use in many regions has a powerful suppressive effect, which current models underestimate (Prentice *et al.*, 2011a).

Wetlands and Drylands

Vegetation growing in hydrologically extreme environments (very wet or very dry) has been the last to be considered seriously in DGVM development (Ivanov *et al.*, 2008; Meron, 2011). Some DGVMs now have explicit representation of wetlands, with distinct PFTs to represent plants adapted to waterlogged conditions (e.g., Wania *et al.*, 2009a, b). Drylands have not been treated in as much detail. But with drylands expanding in some regions (Naito and Cairns, 2011), in part, because of changes in land use (i.e., Knapp *et al.*, 2008; Bollasina and Nigam, 2011), and with the potential for further expansion in some regions due to climate change (MacDonald, 2010; Tietjen *et al.*, 2010; Gutzler and Robbins, 2011), the modeling of drylands is assuming greater importance.

Fire is a crucial intermediary in some seasonally dry environments (e.g., mediterranean-type and savanna ecosystems: Bond *et al.*, 2003, 2005), and is modeled explicitly in several DGVMs. In the drylands, by contrast, fire is rare or absent because of the lack of a continuous fuel bed. Vegetation in desert environments depends on several processes that are not represented at all in most DGVMs. Facilitation or the 'nursery effect' describes the ability of pioneering plants to provide shade, shelter, and soil moisture to less drought-tolerant plants (Prentice and Werger, 1985; Brooker *et al.*, 2008). Once established, these newly established plants provide further shade, shelter, and moisture to additional plants, resulting in the grouping of vegetation in clusters across arid landscapes. Clustering is also promoted by microtopography, leading to a separation of 'run-off' and 'run-on' zones, the latter able to support (denser) vegetation (Vasquez-Mendez *et al.*, 2010; Aerts *et al.*, 2006). Hydraulic redistribution is the passive release of water from deep tap roots into upper soil horizons when hydraulic conductivity decreases at night (Katul and Siqueira, 2010). It is most pronounced in areas with a strong gradient of soil water potential within the rooting zone. Water is generally distributed from wet to dry regions within the soil profile. Plants with deep roots are therefore able to provide soil moisture to neighboring shallow-rooted plants. Both facilitation and hydraulic redistribution can result in a positive feedback on plant establishment.

Surprisingly, simulations including hydraulic redistribution have been initially conducted not for arid regions but rather for wet environments like the Amazon Basin that experience only periodic drought. Recent simulations incorporating the effect indicate that the overall consequences for vegetation performance depends primarily on the duration of drought (Wang, 2011; Wang *et al.*, 2011). When drought periods are short, hydraulic redistribution increases transpiration and NPP; however, when drought is prolonged, hydraulic redistribution ultimately reduces NPP because it accelerates the depletion of deep soil water storage. Simulations of the Amazonian forest incorporating the effects of deep roots in extracting water from soils near the groundwater table show that deep root uptake of water was limited, due to

the high concentration (70–90%) of clay in the soils and a high soil-to-root resistance to water uptake (Markewitz *et al.*, 2010). The lack of representation of facilitation, run-off/run-on, and hydraulic redistribution is a likely contributory explanation for the relatively poor ability of current DGVMs to represent the vegetation in arid and semiarid regions such as the southwestern USA, southern Africa, and interior Australia.

Another limitation of DGVMs' ability to simulate dryland vegetation is the very short list of PFTs used by current models. The diversity of plant adaptations to life in the desert is an often remarked-on feature of these environments, but today's DGVMs do not account for characteristic traits of dryland plants such as succulence, leaflessness, traits that avoid excessive absorption of solar radiation such as reflective hairs, waxy epidermis, and vertical leaf insertion, and the specialized form of photosynthesis known as Crassulacean Acid Metabolism.

Fields of Application of DGVMs

Carbon Cycle

The story of modern carbon cycle science begins with the first precise measurement of annually and seasonally varying CO₂ concentrations by Keeling (1958), who was thus able to confirm a hypothesis (that CO₂ concentration was rising) which had first been put forward more than half a century earlier. Since the 1980s, several overlapping networks of remote atmospheric measurement stations (for CO₂, other trace gases and valuable tracers of the carbon cycle such as the stable carbon isotope composition of atmospheric CO₂) have been maintained. The resulting global network of measurement stations contains far more information than could be extracted from Keeling's original two, at Mauna Loa (Hawaii) and the South Pole. These records already showed that in addition to the year-on-year increase of CO₂ concentration, there is a seasonal cycle, which is much stronger at Mauna Loa than at the South Pole and which shows opposite phase in the two hemispheres. Keeling quickly realized that this cycle is caused by the 'breathing' (seasonal CO₂ uptake and release) of the terrestrial biosphere. The great value of the more extensive CO₂ observation network that exists today is that it provides more highly resolved information about the latitudinal variations in this seasonal cycle, and even about longitudinal patterns (albeit these are smoothed by rapid mixing), which give information about the spatial patterns of sources and sinks of CO₂.

This information is valuable as a test of DGVMs, since they explicitly predict a spatial and seasonal pattern of CO₂ uptake and release. To use this information, however, it is necessary to involve an atmospheric transport model to translate the signals at grid cells to a combined signal at a remote place in the atmosphere. A simple recipe for this comparison, presented by Heimann *et al.* (1998), provides a powerful (but under-used) benchmark for DGVMs and coupled climate-carbon cycle models (Prentice *et al.*, 2000a, Cadule *et al.* 2010). The ability to reproduce this seasonal signal at different latitudes is a major achievement of DGVMs.

The rate of increase in CO₂ concentration varies greatly from year to year. These variations bear the imprint of the El

Niño-Southern Oscillation (Bacastow, 1976), and of large volcanic eruptions such as Mount Pinatubo that have significant transient effects on climate (Mercado *et al.*, 2009). The interannual variability of the CO₂ growth rate has been shown to be dominated by variations in the fraction of anthropogenic CO₂ that is taken up by the land (McGuire *et al.*, 2001; Denman *et al.*, 2007). Thereby it provides a further test and demonstration of the capabilities of DGVMs (Cadule *et al.* 2010).

The longer term mean rate of uptake of CO₂ by the land, which can be separated from the ocean component by independent measurements of O₂ concentration or the stable isotope composition of atmospheric CO₂ (Keeling and Shertz, 1992; Keeling *et al.*, 1996; Battle *et al.*, 2000; Prentice *et al.*, 2001), is a further quantity that can be predicted by DGVMs. It is modeled as a direct consequence of the continuing CO₂ rise and its fertilizing effect, combined with the residence time of carbon in the biosphere (Friedlingstein *et al.*, 1995; Kicklighter *et al.*, 1999; McGuire *et al.*, 2001; Prentice *et al.*, 2001). The residence time is long enough to ensure that the size of the carbon pool does not keep up with the rate of increase in growth. This historical rate of carbon uptake by the land is potentially an important constraint on models' future projections of carbon uptake (Arora *et al.*, 2009). In Friedlingstein *et al.* (2006), the models with the lowest and highest uptake rate of atmospheric CO₂ in the future, respectively, under- and overpredicted the rate of CO₂ uptake during recent decades, suggesting that this very simple carbon budget criterion could provide one way to identify poorly performing models.

The IPCC Fourth Assessment Report (Denman *et al.*, 2007) highlighted the uncertainty in the modeled terrestrial carbon cycle feedbacks, represented by these coupled climate-carbon cycles. It is a matter of urgency that the uncertainty be reduced, which will be possible through systematic comparison of model outputs with the most relevant observations – i.e., atmospheric carbon cycle measurements.

Hydrology

Hydrology is a relatively new field of application for DGVMs (see e.g., Rost *et al.*, 2008; Murray *et al.*, 2011). But *global hydrological models* have been developed in parallel with DGVMs, primarily for the assessment of large-scale regional changes in freshwater availability in a changing climate, and contain many of the same processes (e.g., Arnell, 1999a, b). The potential advantage of using a DGVM for water resources assessment is that a DGVM explicitly represents changes in vegetation cover, leaf area, stomatal conductance, and transpiration resulting from changes in climate and atmospheric CO₂ concentration, in a biologically and physically consistent way.

However, additional work needs to be done to bring DGVMs 'up to speed' for hydrological applications. Foremost, it is essential to use hydrological observations (streamflow measurements) as a benchmark for the terrestrial runoff simulated by DGVMs (Murray *et al.*, 2011). This will bring a dual benefit, as runoff is highly sensitive to the representation of vegetation (being a relatively small fraction, about 1/3 of

precipitation globally and much less in the drylands) and is therefore powerful as a test for the model's performance in simulating vegetation function. Furthermore, hydrological modelers have developed methods to improve runoff simulation by taking account of heterogeneity in the hydrological properties of the land surface. This approach has been used in LSMs (Liang *et al.*, 1994; Liang and Xie, 2001). In one case where the concept of variable infiltration capacity was applied to the LPJ DGVM, it was shown to greatly improve the model's simulation of runoff (Li and Ishidaira, 2011). And just as atmospheric transport modeling is the key to bringing DGVM predictions into comparison with atmospheric measurements, river routing modeling will be the key to bringing DGVM predictions into comparison with streamflow measurements.

Trace Gases and Aerosols

The terrestrial biosphere is the predominant source of the powerful greenhouse gases methane (CH_4) and nitrous oxide (N_2O); the precursors of ozone (O_3), which (when present in the surface atmosphere) is a potent greenhouse gas as well as a toxic pollutant, and reactive gases that indirectly influence greenhouse gas concentrations through atmospheric chemistry, including carbon monoxide (CO), nitric oxide (NO) and volatile organic compounds – predominantly hydrocarbons (isoprene, C_5H_8 and monoterpenes, $\text{C}_{10}\text{H}_{16}$) and methanol (CH_3OH). These natural atmospheric constituents are produced variously by direct emission from leaves, soil microbial transformations of organic matter derived from plants, and in fires. Global modeling of the terrestrial sources (and in some cases, sinks) of these compounds is a natural extension of DGVMs. Arneth *et al.* (2010a) reviewed the state of the art in this field.

Modeling methane emissions has proved to be a complex challenge as it required the explicit simulation of wetlands, including PFTs adapted to low-oxygen environments, and the microbial processes specific to wetlands and waterlogged mineral soils (Gedney *et al.*, 2004; Wania *et al.*, 2009a, b, 2010; Spahni *et al.*, 2011; Huntingford *et al.*, 2011). For Earth system modeling, it is important to model not only processes within wetlands and wet soils, but also the hydrological conditions that allow permanent wetlands to be sustained (Ringeval *et al.*, 2010). This is a new frontier for DGVMs.

In addition to trace gases, terrestrial ecosystems provide the main source for some types of atmospheric aerosol that influence climate. Airborne dust has many different, both 'good' and 'bad' consequences, including providing a natural source of iron to fertilize marine ecosystems (Harrison *et al.*, 2001). Dust is emitted from unvegetated parts of the land surface. Its emissions are thus controlled by vegetation. Dust modeling depends critically on modeling vegetation density and phenology (Tegen *et al.*, 2002) as well as geomorphic factors that control the emission of dust from nonvegetated surfaces (Bullard *et al.*, 2011). VOC emissions also contribute to secondary organic aerosol, a complex and poorly understood atmospheric constituent whose physical importance has only recently been recognized. Earth system models are just beginning to integrate these many aspects of the interaction of the atmosphere and biosphere, all of which depend on the

representation of plant and ecosystem processes by the embedded DGVMs.

Biophysical Land–Atmosphere Interactions

Responses of vegetation to changes in CO_2 and climate bring about changes in the physical properties of the land surface, which in turn influence climate. These feedback effects become explicit when DGVMs are coupled with climate models (e.g., Foley *et al.*, 1998; Betts, 2001; Betts *et al.*, 2007b; Cowling *et al.*, 2007a; Roy, 2009; Lunt *et al.*, 2010; Quillet *et al.*, 2010; Delire and de Noblet-Ducoudré, 2011). The three most important land-surface variables that influence local climate, and change according to vegetation properties, are the surface albedo; surface energy partitioning; and surface roughness. Surface albedo (the reflectivity of the Earth's surface) varies according to vegetation type, with deep green vegetation (such as evergreen forests) absorbing more solar radiation than light-colored vegetation such as grassland or desert. Typical surface albedos are for coniferous forest 0.05–0.15, deciduous forest 0.15–0.20, grassland 0.16–0.26, cropland 0.18–0.25, and bare ground 0.05–0.40 depending on soil type and wetness (Bonan, 2002). Snow cover dramatically increases surface albedo in treeless vegetation, but less so in forests (especially boreal evergreen forests) where dark plant surfaces remain above the snowpack (snow masking). Surface energy partitioning refers to the amount of latent heat produced relative to sensible heat. Latent heat is the energy required to change the phase of water (denoted Q_E); sensible heat is the energy available to warm the surface (denoted Q_H). The partitioning of surface energy is expressed by the Bowen ratio (Q_H/Q_E). The Bowen ratio is influenced by the rate of transpiration, which in turn depends on leaf area index (the ratio of leaf surface area to underlying ground area) and stomatal conductance (per unit leaf area). Surface roughness is related to the theoretical height at which wind speed above the canopy is zero, defining the maximum height of atmospheric mixing. In general, surface roughness for grass is smaller than for forests. Surface roughness ultimately influences surface energy partitioning as a wind gradient (air mixing) is required to maintain the gradient that drives transpiration (low vapor pressure of water outside the leaf, relative to inside). All three properties can be altered by vegetation dynamics and thus can potentially induce feedback responses in a climate model.

Uncertainties in the behavior of the physically coupled vegetation–atmosphere system, however, are at least as large as those for the carbon cycle. The strength of the coupling between land-surface properties and the hydrological cycle in the atmosphere differs greatly among climate models (Seneviratne *et al.*, 2006; Denman *et al.*, 2007), so the simulated climate effects of a given vegetation change can be very different depending on the climate model. Climate–vegetation feedbacks in a future climate have been indicated to cause severe shrinkage of the Amazon Basin rainforests (Betts *et al.*, 2004; Cox *et al.*, 2000, 2004; Harris *et al.*, 2008). But a change in the recycling of water in tropical rainforests can in principle either increase or decrease the total areal coverage of vegetation, depending on its cause. Recent simulations in general have shown less Amazon dieback (Huntingford *et al.*, 2008;

Rammig *et al.*, 2010; Salazar and Nobre, 2010) than earlier ones. The general uncertainty regarding biophysical feedbacks also afflicts attempts to quantify the consequences of past and present land use (Betts *et al.*, 2007a), which have shown major discrepancies among models (Pitman *et al.*, 2009).

One question that has received considerable attention, but incomplete resolution, is the influence of 'physiological forcing' of CO₂ on climate (Boucher *et al.*, 2009; Andrews *et al.*, 2011). Physiological forcing refers to changes in land-surface properties brought about by the response of plants to changes in CO₂ concentration, which can be contrasted with 'physical forcing' of climate due to the greenhouse effect of CO₂. The physical forcing is certainly larger, but modeling suggests that physiological forcing is not negligible. Early sensitivity experiments, where land-surface properties in a climate model were varied, suggested that reduced stomatal conductance due to increased CO₂ concentration led to reduced transpiration and increased surface warming (Sellers *et al.*, 1997; Bounoua *et al.*, 1999). This is not the whole story, however, because physiological effects of CO₂ (increased NPP and reduced stomatal conductance) can also lead to an increase in LAI (Cowling and Field, 2003), with compensatory effects on transpiration and climate (Betts *et al.*, 1997). In general, if LAI increases then the Bowen ratio decreases, due to an increase in rate of transpiration and production of latent heat, opposite to the effect of reduced stomatal conductance (Reyers *et al.*, 2011).

Bounoua *et al.* (2010) continued the theme of using sensitivity experiments to assess the physiological forcing of CO₂. This study attracted media attention because in one scenario, greatly enhanced evapotranspiration led to a substantial reduction in the overall global warming due to CO₂. However, this scenario assumed that the down-regulation of Rubisco capacity would lead to a large increase in LAI. There is no evidence for such an effect.

Many additional vegetation–climate interactions are likely to arise as a result of the physical forcing of climate. For example, a longer snow-free season will create a positive albedo feedback in high latitudes. Forest expansion in high latitudes, as simulated by DGVMs (Cramer *et al.*, 2001), will create additional positive feedback due to snow masking. And if DGVM-simulated vegetation dynamics are allowed to proceed to equilibrium with a new, high CO₂ concentration, one set of climate model simulations has suggested that the 'greening' effect promoted by reduced stomatal conductance may lead to additional warming, due to albedo feedback (O'ishi *et al.*, 2009).

The balance of conflicting effects of rising CO₂ is thus still not clear in general, and is likely to differ among regions. Yet this balance has wider implications, for example, for hydrology (Betts *et al.*, 2007b). Gedney *et al.* (2006) attributed an increase during recent decades in runoff relative to precipitation to the effect of CO₂ on stomatal conductance, but this conclusion has been disputed by Piao *et al.* (2007) and several others. Resolution of this issue will not come through more sensitivity experiments, but it will require careful comparative evaluation of the various responses of vegetation to CO₂ in DGVMs. Vegetation–climate feedbacks are a fertile field for the application of DGVMs, but large uncertainties are likely to persist until ways are found to constrain the strength of the

coupling between the land surface and the atmosphere. In addition, there may be interactions between processes at the local ecosystem versus the landscape scale that could bring about threshold behavior in the coupled system, but which are not yet represented in DGVMs (e.g., Brovkin *et al.*, 2009; Dekker *et al.*, 2010; Rietkerk *et al.*, 2011).

Vegetation Structure, Composition, and Biodiversity

There have been very few analyses of the global impacts of projected twenty-first century environmental changes on vegetation distribution, structure, and composition using DGVMs (but see: Neilson *et al.*, 1998; Scholze *et al.*, 2006; Gonzalez *et al.*, 2010). This is surprising, given that this was one of the principal applications originally envisaged for DGVMs. It may be that the lack of regional detail implied in the use of a limited set of PFTs, and other deficiencies noted above, has inhibited such effort. If so, then it will be important to develop more realistic representations of the diversity of plants. The authors suggest that this will be possible, given the dramatic recent improvements in the availability of trait data on wild plants. It will require a bold increase in the diversity of plants represented within DGVMs, whether as discrete PFTs, or via plasticity in trait values, or (most likely) a combination of the two.

Meanwhile, the dominant type of model used for regional assessments of climate change impacts on biodiversity has been quite different, namely *species envelope models* developed for one species at a time based on empirical relationships between geographic distributions and climate variables (e.g., Thomas *et al.*, 2004; Thuiller *et al.*, 2005). The list of problems and deficiencies with this approach is rather long (Pearson and Dawson 2003; Dawson *et al.*, 2011). Nevertheless, there is valuable climatic information in species range limits. Alternative approaches have been developed whereby 'bioclimate variables' for predictive purposes are specified *a priori* from process considerations, then species' limiting values fitted empirically (e.g., Sykes *et al.*, 1996). Better still, independent observations and experimental evidence can be used to predict species' limits, so the predictions can be tested using the observed limits (e.g., Chuine and Beaubien, 2001; Morin *et al.*, 2007).

One limitation of conventional species envelope models is that they provide no way to represent the potential modification of range limits by CO₂ concentration. Keenan *et al.* (2011) showed that this makes an important difference. Predictions of the effect of climate change on tree species distributions in the Mediterranean region were found to depend critically on whether or not raised CO₂ concentration was allowed to compensate for decreased rainfall. There is a potential to merge elements of process-based range limit modeling with representations of physiological processes used in DGVMs. This has been done for regional applications of the LPJ-GUESS DGVM (Hickler *et al.*, 2012) and provides (among other benefits) a natural way to build in CO₂ effects on species' potential ranges.

A quite different approach to modeling has attempted to represent explicitly the controls on the number of species that can be 'packed' into a given environment (Kleidon and

Mooney, 2000; Kleidon *et al.*, 2009; Reu *et al.*, 2011). This approach has been successful in reproducing the broad global patterns of plant species diversity, and deserves consideration as an element of future DGVMs.

Interpreting the Past: Toward a Deeper Understanding of the Natural World

Vegetation, Climate, and Carbon Cycle Feedbacks During the Quaternary Period

The major controls on the climate variations of approximately the past million years are relatively well understood. There is a well-developed theory for how variations in the astronomical parameters of the Earth (orbital eccentricity, precession and axial tilt) combine with variations in ice-sheet extent, which are heavily lagged responses to orbital variations, and natural variations in the concentrations of the greenhouse gases CO₂, methane, and nitrous oxide, which are directly measured in the air bubbles trapped in ice cores (the record is now 850,000 years long): see the review by Harrison and Bartlein (2012). The continuous time sequence of climate changes in different latitude bands and regions has been modeled over the last deglaciation, i.e., the period since the last glacial maximum, 21 thousand years ago, using a fast climate model (Timm and Timmermann, 2007). Many standard simulations with climate models have also been made for the iconic periods, the LGM and the mid-Holocene (six thousand years ago), in successive phases of the Palaeoclimate Modelling Intercomparison Project. These two periods have also been a major focus for the synthesis and analysis of palaeodata (e.g., Prentice *et al.*, 2000b; Bartlein *et al.*, 2011).

The main factor that changed between the mid-Holocene and recent preindustrial time was precession. Perihelion in the early to mid-Holocene occurred in boreal summer, leading to increased summer and decreased winter insolation in the mid-latitudes of the Northern Hemisphere. This in turn led to greater land–sea contrast and expanded monsoons in the northern tropical continents, exemplified by the ‘green Sahara’ as manifested in pollen and plant data and relics of former lakes, swamps, megafauna, and human habitation. Much has been written, based on simulations without dynamic vegetation, about the requirement for biophysical feedback (specifically, the reduced surface albedo of a wetter and more vegetated landscape) to explain the full extent of the monsoon expansion (e.g., de Noblet-Ducoudré *et al.*, 2000). However, the more recent application of DGVMs within climate models has changed the picture: the feedbacks appear to be less strong in the available models, and insufficient to explain the data (Harrison and Bartlein, 2012; Wolff *et al.*, 2012). Much depends on the specification of surface albedo for different vegetation types, for example, when surface albedo was modeled based on leaf area index in combination with the state of the soil beneath the forest canopy (increased organic matter, litter, and standing dead biomass), Vamborg *et al.* (2011) could better simulate the increase in Saharan precipitation required to account for the data. Another controversial area concerns the abruptness, or otherwise, of the reinstatement of the Sahara desert, after the mid-Holocene.

The field evidence is contradictory. Strong positive feedbacks could in principle allow an abrupt transition from a ‘green’ to a ‘brown’ state, and this type of dynamics has been simulated with an Earth System model that includes a simple DGVM (Claussen *et al.*, 1999). But analysis with the LPJ DGVM has suggested that an abrupt transition, in response to gradually declining precipitation, may be a consequence of vegetation dynamics alone (Liu *et al.*, 2006, 2007).

The LGM is interesting for the carbon cycle because of the low CO₂ concentration (180–190 ppm, compared with 260–280 ppm during the preindustrial Holocene); long-standing evidence from stable carbon isotopes (reviewed by Prentice and Harrison, 2009) that the terrestrial biosphere stored less carbon then, compared with the Holocene; and new evidence from stable oxygen isotopes that terrestrial GPP was even more strongly reduced in proportional terms (Ciais *et al.*, 2011). The mere presence of large continental ice sheets in North America and northern Europe cannot account for reduced carbon storage at the LGM because a comparable area of continental shelf was exposed, mainly in the tropics. A variety of modeling studies has led to the conclusion that the greatly reduced global forest cover during the LGM can be explained only when physiological effects of CO₂ are considered (Cowling, 1999; Cowling and Sykes, 1999; Bond *et al.*, 2003; Harrison and Prentice, 2003), and that the reduced carbon storage cannot be explained solely by the colder and drier climate (Prentice and Harrison, 2009). In a study using the LPX DGVM and results from four climate models, Prentice *et al.* (2011c) showed that realistic reductions in forest cover, GPP, and carbon storage could be simulated for the LGM. Ciais *et al.* (2011) further showed that the reduction in carbon storage may have been partly compensated by increased storage of inert carbon in permafrost soils.

Paleoecological records contain far more information than these limited ‘snapshot’ studies have used so far. Now that transient climate model simulations over multimillennial periods have become feasible, there is a potential to apply DGVMs through periods of current focus for climate modeling such as the last millennium, the last deglaciation, and the abrupt warming episodes (Dansgaard–Oeschger events) that punctuated the last glacial period. Large-scale analyses of data from these periods have yielded surprising insights, such as the sensitive dependence of biomass burning on small variations in temperature during recent centuries, the very large and rapid decline in biomass burning since the mid-nineteenth century (Marlon *et al.*, 2008; Wang *et al.*, 2010a), and the rapid responses of many global indicators including greenhouse gas concentrations, dust concentrations, and fire regimes to D–O events (Arneeth *et al.*, 2010b; Hopcroft *et al.*, 2011). There is also evidence of remarkably rapid responses of vegetation composition to D–O events (Harrison and Sanchez-Goni, 2010). Reproducing such phenomena will be an important challenge for DGVMs.

Vegetation–Climate Interactions in Deep Geological Time

Studies of the Quaternary period, especially the period from the LGM onwards, have two great advantages: a wealth of accurately dated information, and the fact that very little

macroevolution or natural extinction has taken place on this time scale (Dawson *et al.*, 2011) so that observed biotic transitions can be interpreted based on knowledge of the present-day biota. But there is increasing interest in the climate and vegetation of more distant geological periods, especially periods when global temperatures and CO₂ levels were higher than today.

Climate models can legitimately be used for any geological epoch for which information on paleogeography and atmospheric composition can be supplied. But the land surface is a sticking point for deep time studies. Land-surface models of all kinds, including DGVMs, incorporate information derived from extant plants. We do not yet have the tools to analyze ecosystems composed of ancient plants (Shellito and Sloan, 2006a, b). A number of studies have therefore simply used models designed for modern vegetation. One of the first explicit simulations of ancient ecosystems was an assessment of the recovery time of terrestrial productivity following the meteorite impact that ended the Cretaceous (Lomax *et al.*, 2001). This study accepted the modern biogeography of five PFTs (evergreen and deciduous needle-leaved and broad-leaved trees and a herbaceous understory), so it did not account for the fact that angiosperm trees – with their higher rates of xylem water flow – were far less important in the Cretaceous than they have become since. Donnadieu *et al.* (2009) used the LPJ DGVM, without modification, to simulate vegetation–climate feedbacks in the Mesozoic; as a result they simulate grasslands (including C₄ grasses, with much lower stomatal conductance than C₃ plants) that had not yet appeared on Earth. A study of vegetation–climate feedbacks in the Paleozoic (Horton *et al.*, 2010) removed the grass PFTs from a biogeography model, but nevertheless assumed that the Paleozoic woody plants were appropriately represented by modern trees, despite major differences in leaf and wood anatomy. These are not isolated examples of studies whose findings are rendered moot by the use of models that have been developed for modern plants.

We know from the fossil record that ecosystems of past geological periods were unlike modern ones in functionally important ways (e.g., Hermann *et al.*, 2011). Angiosperms did not expand greatly until the beginning of the Cenozoic (Magallon and Castillo, 2009), but during the Cenozoic angiosperms largely out-competed the gymnosperms that were widespread forest dominant in the late Cretaceous (Coiffard and Gomez, 2010). The evergreen needle-leaved gymnosperm trees of today are cold-adapted and generally confined to northern temperate and boreal latitudes, whereas those of the Cretaceous were warm-adapted and found at all latitudes (Escapa *et al.*, 2011; Hermann *et al.*, 2011; Leslie, 2011). Tree ferns and ground-covering surface ferns were plentiful in the Cretaceous, whereas today they are a very minor component of vegetation globally (DiMichelle and Phillips, 2002). These situations raise intriguing questions about the extent to which the predominant plant taxa in different epochs were particularly well adapted to environmental conditions and, conversely, the extent to which past climates and environments were influenced by the biophysics of the plants of their time. To what extent did ancient trees recycle water inward from coastal regions? Did the properties of ancient PFTs contribute to the higher atmospheric humidity levels reconstructed for the

Mesozoic? Did falling CO₂ levels, with the attendant need for more rapid water conduction, drive the expansion of the angiosperms during the Cenozoic? Such questions cannot be addressed with contemporary plant models.

Indicative answers to ‘what if’ questions about ancient ecosystems can sometimes be provided nevertheless by sensitivity analyses using currently available models. Herold *et al.* (2011), wishing to determine whether the Australian monsoon climate could be simulated for the early to mid-Miocene, ran simulations with grassland covering the Australian continent; forest covering the continent; and more realistic cases incorporating broad-leaved forests, shrublands, and mixtures of these vegetation types. Lunt *et al.* (2007) simulated the distribution of C₄ grasses in the late-Oligocene and found that the model predicted greater C₄ distributions relative to the preindustrial (curiously, a result opposite to what the paleodata show). Global simulations without C₄ grass were carried out to assess the implications of C₄ grass evolution for regional energy and water exchanges during the Miocene (Cowling *et al.*, 2007b). Cowling *et al.* (2009) also conducted hypothetical global simulations in which all plants used C₄ photosynthesis, to determine the consequences for the global distribution of sensible and latent energy.

Some recent simulations of climate and vegetation during the late Miocene have paid more specific attention to representing past vegetation types. Boreal forest was simulated to extend beyond 80° N and temperate forest above 60° N, consistent with the fossil record (Pound *et al.*, 2011). Pound *et al.* (2011) concluded that tropical latitudes were characterized by altered distributions of tree types found there today, whereas northern latitudes contained tree types not found there today. François *et al.* (2011) incorporated nonextant warmth-requiring tree PFTs in their modeling of the late Miocene in Europe. Several simulations of Pliocene climate and vegetation have been conducted with DGVMs embedded within GCMs (Jost *et al.*, 2009; Salzmänn *et al.*, 2008; Haywood *et al.*, 2002; Haywood and Valdes, 2006), representing a flora more similar to that of the Quaternary, so fewer problems arise with the application of current models.

Confusion can be caused if words we use today to describe vegetation are applied to ancient vegetation. For example, terms like ‘xeric adapted’ have been used to apply to Cretaceous plants. But most of the extant desert plant lineages (e.g., agaves, ice plants, and cacti) evolved more recently, between the Eocene and the Miocene (Arakaki *et al.*, 2011). Furthermore, large variations in atmospheric CO₂ concentration have occurred during the period since the origin of land plants. These have been linked to large variations in the density and morphology of stomates (e.g., Franks and Beerling, 2009) implying that plant water relations have been very different indeed at past high CO₂ levels. Thus, it cannot be assumed that morphological features relating, for example, to water stress have the same quantitative significance in the deep past as they do today. To understand the function of ancient plants and vegetation, it will be necessary to analyze and model plant adaptations from a process-based, biophysical perspective.

In conclusion, the authors propose that the modeling of ancient ecosystems will become a highly rewarding field of investigation if serious attention is paid to the representation of ancient plants in land-surface models and DGVMs. The key

point is that modeling needs to be based on biophysical principles, and on measurable traits of ancient plants. It should *not* be based on the observed distributions and habitat preferences of extant plants. Many relevant morphological traits fossilize well, and there is a growing literature based on the compilation of measurements such as leaf size and dissection, petiole diameter, bole diameter, root length and diameter, stomatal density and aperture, leaf anatomy and the diameters of xylem conducting elements (which govern the hydraulic properties of stems) in fossil plants. All of these traits have a direct relevance to plant biophysics and could be used in a 'next generation' DGVM, if such a model were to be formulated in terms of the observed characteristics of plants – whether modern or ancient.

Prospects

DGVMs are a necessary tool for modeling and understanding vegetation responses to environmental changes, past, present, and future. They are also needed to link different kinds of Earth System observations (such as climate, the carbon cycle, land-surface properties, and atmospheric composition), and they are an indispensable part of the toolkit required for modeling the interactions among different Earth System components. They are still a relatively new class of model, however, and they need a good deal of further development. There is a potential to reduce the current (large) discrepancies among models by paying greater attention to systematic benchmarking of models against large-scale observations (including remotely sensed data, atmospheric measurements and hydrological measurements). The utility of DGVMs could be expanded by making better use of the 'data revolution' in comparative plant ecology. Some uncertainties in modeling reflect uncertainties in the underlying science (for example, carbon–nitrogen cycle coupling). The authors suggest that modeling has a proactive role to play in such cases, by analyzing the consequences of alternative hypotheses rather than simply assuming a particular interpretation of the evidence.

The authors propose that the next generation of DGVMs will be not necessarily be more 'complex' than the present one, but future models will take better account of the observed diversity and morphology of plants and their varied responses to environmental triggers, including (especially) aridity and fire. DGVMs will continue to be applied to past vegetation and climate, with emphasis on transient changes in plant community composition and fire in recent climates, and the interplay of plant morphological and functional evolution with climate, atmospheric composition and the global hydrological cycle in ancient climates. This last objective will require closer attention to the biophysical representation of ancient plants.

Ecosystem Function Measurement, Terrestrial Communities

Sandra Díaz, Universidad Nacional de Córdoba – CONICET, Córdoba, Argentina

© 2013 Elsevier Inc. All rights reserved.

Glossary

Biodiversity Number, abundance, composition, spatial distribution, and interactions of genotypes, populations, species functional types and traits, and landscape units in a given system.

Ecosystem Conceptual view of an assemblage of organisms and of physical and chemical components in their immediate environment, and the flow of materials and energy between them.

Ecosystem functioning Flow of energy and materials through the arrangement of biotic and abiotic components of an ecosystem.

Ecosystem stability Capacity of an ecosystem to persist in the same state. It has two components. Ecosystem resistance

is the ability to stay in the same state in the face of perturbation. Ecosystem resilience is the ability to return to its former state following a perturbation.

Functional diversity Value, range, distribution and relative abundance of the functional traits of the organisms in a given ecosystem.

Resource dynamics Inputs, outputs, and internal cycling of key resources, such as carbon, water, and mineral nutrients, in an ecosystem.

Trophic transfer The amount of biomass and/or energy which is transferred from the primary producers to the herbivore-based food chain rather than directly from plants to detritivores.

Why Measure Ecosystem Functioning?

Ecosystem functioning involves processes such as primary production, trophic transfer from plants to animals, nutrient cycling, water dynamics, and heat transfer. This term refers to functioning in equilibrium, namely the amount (how much), the rate (how fast), and sometimes the seasonal variations of these processes. It also includes the responses of ecosystem processes to perturbation, resilience, and resistance. Ecosystem processes provide essential benefits to humankind, also called ecosystem services, such as food, fiber, fodder, fuel, water provision and detoxification, amelioration of weather, soil formation, retention of carbon that otherwise would be released into the atmosphere contributing to climate change, and medicinal, recreational, and cultural resources. As the impacts of changes in the quantity and quality of benefits provided by terrestrial ecosystems to humankind come to the focus of public attention, it is increasingly obvious that their value in the market, if any, greatly underestimates their true value to society. Therefore, measurement of an ecosystem's structural and functional properties such as how much animal biomass an ecosystem can produce or how much water, carbon, and nutrients can be retained *in situ* are key inputs for an evaluation of ecosystem services to humankind. Concepts, methods, and data retrieval on ecosystem functioning have progressed enormously in the past few decades, and today an impressive body of quantitative information on flows and stocks of materials and energy through a wide spectrum of ecosystems is available. Much less is known, however, of the effects of perturbations on these processes, in particular of thresholds beyond which the ecosystem can no longer recover its former basic properties. Physiological processes underlying biomass production, water balance, and nutrient cycling are well understood. However, there are still many theoretical and methodological difficulties and information gaps in the understanding – and thus the prediction – of processes at coarser scales of time (decades or centuries) and space

(ecosystems, landscapes, and biomes). To determine how the biosphere will respond to the changes in climate, atmospheric composition, and land use projected for the future, a better understanding of ecosystem properties at these scales is vital.

Ecosystem Resource Dynamics

Three main processes that are linked to the acquisition and loss of chief resources for terrestrial ecosystems (light, carbon, water, and mineral nutrients) will be analyzed here. These processes are biomass production (primary productivity and trophic transfer), nutrient (especially nitrogen) cycling, and water dynamics. There is a strong association between water flow, carbon assimilation, and nutrient uptake by a plant. Given that carbon dioxide (CO₂) input and water output occur through open stomata, and nutrient and water uptake occur through root hairs and fine roots, they are inextricably linked. Nutrient availability controls the increase in plant mass, and incorporation of mineral nutrients into biomass is not possible without carbon assimilation. The derived processes at the ecosystem level, namely biomass production, water balance, and nutrient cycling, are therefore closely linked and basically regulated by net radiation, temperature and precipitation, soil composition and structure, and the kinds of plants that are present. Any consideration of carbon, nutrient, or water balance in isolation is probably artificial. The examples presented here are described in different sections for the sake of clarity, but they highlight the strong interdependence of these processes.

Approaches to Analysis and Measurement of Ecosystem Functioning

Whole-Ecosystem Approaches and Approaches Based on Community Structure and Composition

The measurement of ecosystem functioning focuses on the sizes of major pools of resources, such as water, carbon, and

mineral nutrients, and on the rates of flows connecting them. In the 1970s compartmental models become an important tool in 'systems ecology' (illustrations of this view can be found in the classic textbook on ecology by E.P. Odum, 1971). In these models, boxes represent pools or stocks (usually major trophic levels), and arrows signify the flows between them. This still represents a first and very useful approximation. However, pools are often treated as 'black boxes' in which only the general size, and not the internal composition, is important. This often makes this approach too coarse for the management of real situations and of little predictive value for novel situations. This is because in many the whole pool is not altered, but instead subtle intrapool changes occur until a threshold is reached or substances are chemically altered or sequestered because organisms that are members of the same pool (e.g., primary producers, detritivores, and primary or secondary consumers) often differ in the ways they affect, and respond to other biotic or abiotic compartments in the ecosystem. Hence other approaches have increasingly focused on the internal composition of pools (what taxa or functional groups are present within the boxes and in what abundance) and how changes in that composition can alter flow rates between pools (see for e.g., the highly innovative textbook by Chapin *et al.*, 2011).

Measurement of Short-Term Resource Dynamics and Long-Term, Large-Scale Ecosystem Processes

Some methods of ecosystem analysis emphasize the measurement of short-term process rates (e.g., photosynthesis, nutrient uptake, and evapotranspiration), whereas other methods emphasize the measurement of the size of pools accumulated as a result of these processes, with or without consideration of their internal components (e.g., biomass production, nitrogen stocks in different compartments, and water use efficiency integrated over a whole season) (Table 1). The choice depends mostly on the objectives pursued and on the scale of observation selected. However, as a general rule, methods based on short-term flows provide more mechanistic understanding, but they do not provide a clear picture of what happens at the time and space scales most relevant to ecosystem functioning (meters to thousands of kilometers and months to decades or centuries). Measurements of flow rates (*F* measurements in Table 1) tend to be very precise but highly variable. They give a snapshot of ecosystem functioning, but they do not necessarily reflect processes over a growing season or longer. For example, short-term (hourly or daily) variation in gas exchange per leaf area is not directly reflected in annual biomass production. Plant growth and vegetation productivity cannot be directly equated with leaf photosynthetic rates. The productivity of plant communities is determined more by the amount of photosynthetic tissue (which is in turn controlled by carbon allocation) than by photosynthetic rate. There is often only a slight relationship between these two parameters. Gas exchange measures the instantaneous plant performance, whereas growth necessarily integrates along time and reflects plant allocation patterns. At the community level, additional regulations occur; therefore great caution is necessary in drawing ecosystem-level conclusions on the basis of leaf-level ecophysiological processes. For example, a 10- to 40-fold

difference between species in maximum rates of photosynthesis at the leaf level is reduced to only a factor of two to four at the primary production level between different forest types.

Therefore, for responses at the whole-ecosystem level, methods that focus on changes of pools (*P* measurements in Table 1) are usually more meaningful and convenient. This point is illustrated by Figure 1 and by some examples of the use of different methods for assessing biomass production at different scales (see Biomass Production). An example is provided in Figure 2. A long-term study of the responses of tundra-dominant plants to different treatments showed that processes that are readily integrated at annual time steps (shoot growth, mortality, and allocation) were more useful than instantaneous physiological measurements in predicting decadal vegetation changes. Strong treatment effects on photosynthetic rate (Figure 2(a)) and nutrient uptake were poorly related to longer term changes in production and nutrient concentration (Figure 2(b) and 2(c)). This was probably due to the operation of buffering mechanisms (e.g., allocation, nutrient relations, altered phenology, interspecific interactions, and positive and negative feedback mechanisms) that compensate for immediate physiological responses to the environment.

Some methods are increasingly used that are intermediate or bridge the gap across scales and therefore partially defy the framework given above. A prominent example is micro-meteorological methods that measure the net water and carbon exchange between the canopy and the atmosphere (e.g., the eddy covariance and eddy accumulation methods). These are flow-based methods, which typically work at time scales of hours and spatial scales of a few square kilometers, and are used to integrate leaf- and plot-level fluxes with scales relevant to global climate modelers (Sala *et al.*, 2000).

Biomass Production

Net primary production (NPP) is strictly defined as the difference between the energy fixed by autotrophs and their respiration, and it is most commonly equated to increments in biomass per unit of land surface and time. Because the increment in biomass over a given time depends on the rate at which new biomass is produced and also on the initial amount of carbon-assimilating photosynthetic tissue, stands with a large standing biomass often show higher NPP than stands with lower biomass. Therefore, another useful concept is that of relative productivity rate, or the time needed by a vegetation stand to produce its standing biomass. For example, the estimated relative productivity rate for a dry tropical forest can be many years, whereas in an annual grassland it is less than 1 year.

The fate of assimilated carbon – that is, whether it is allocated to increase the pools of aboveground or belowground biomass, root exudates, litter, soil organic matter, grazers, symbionts, or parasites – varies strongly between ecosystems, depending on prevailing climatic conditions, disturbance regimes, and allocation patterns of dominant plant functional groups (Figure 3). It should be noted that NPP is not the same as Net Ecosystem Productivity or NEP. As stressed by

Table 1 Some examples of ecosystem-level measurements with emphasis on short-term flow rates (F) and on longer term pool sizes (P)^a

Parameter measured	Usual units	Techniques	Emphasis
<i>Biomass production</i>			
Photosynthesis	$\mu\text{mol CO}_2 \text{ cm}^{-2} \text{ s}^{-1}$ or $\text{mg CO}_2 \text{ m}^{-2} \text{ h}^{-1}$	Gas exchange systems (CO_2 , O_2), or simultaneous H_2O and CO_2 exchange	F
Standing biomass	g m^{-2} or t ha^{-1}	Harvest at the end of growing season	P
Productivity	$\text{g m}^{-2} \text{ year}^{-1}$ or $\text{t ha}^{-1} \text{ year}^{-1}$	Sequential harvest; equations including climatic and soil factors; satellite imagery	P
Cover or frequency	% ground area (cover); % total interception (frequency)	Estimation through nondestructive measurement, which can be converted into units of biomass using allometric equations developed on similar neighboring individuals that are destructively harvested	P
<i>Trophic transfer</i>			
Consumer biomass	g or kJ m^{-2} ; t ha^{-1}	Harvest (with or without replacement); equations including NPP	P
CO_2 efflux from respiration (estimates microfaunal biomass)	$\mu\text{mol CO}_2 \text{ m}^{-2}$ or $\text{mm}^{-3} \text{ s}^{-1}$	Gas exchange measurements	F
Secondary productivity	g or $\text{kJ m}^{-2} \text{ year}^{-1}$; $\text{t ha}^{-1} \text{ year}^{-1}$; No. animals $\text{m}^{-2} \text{ year}^{-1}$	Sequential harvest (with or without replacement); animal countings; equations including NPP	P
Consumption	g or $\text{kJ m}^{-2} \text{ year}^{-1}$; $\text{t ha}^{-1} \text{ year}^{-1}$; % plant tissue; % leaf surface	Plant harvest in herbivore-free and grazed situations; estimation of proportion of plant tissue removed; equations including NPP	P
<i>Nutrient cycling</i>			
Decomposition through biomass loss	% initial dw loss	Sequential weighing of litter samples	P
Decomposition through CO_2 efflux from soil or jars	$\mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$ or $\mu\text{g CO}_2 \text{ g dw substrate}^{-1} \text{ h}^{-1}$	Gas exchange system (soil-only control samples or isotope labeling sometimes used in order to distinguish from root respiration)	F
Nutrient status	Mg nutrients g dw^{-1} or % nutrient dw	Harvest followed by chemical analysis; estimation through remote sensing	P
Nutrient use efficiency in litter (amount of biomass produced per unit of nutrient expended and lost; it reflects initial leaf status and efficiency of nutrient resorption)	kg dw mol N^{-1} in litter	Harvest followed by chemical analysis	P
Nutrient uptake	Mg nutrient $\text{g dw}^{-1} \text{ year}^{-1}$	Change in nutrient pool in live biomass over time interval; estimated through sequential harvest followed by chemical analysis of samples	P
Nutrient uptake potential	μg radioisotope $\text{g}^{-1} \text{ h}^{-1}$; pg radioisotope $\text{mg}^{-1} \text{ min}^{-1}$	Soil labeling with radioisotopes such as ^{32}P , ^{33}P , and ^{42}K followed by monitoring of isotope appearance in plant tissue	F
N transformations in the ecosystem (e.g., 'tightness' or 'openness' of nitrogen cycle)	$\delta^{15}\text{N}$ (‰)	Ratio of stable isotopes ^{15}N to ^{14}N in plant material compared with standard (air) using mass spectrometer	P
Nitrogen in soil available to plants	$\text{NO}_3^- + \text{NH}_4^-$ ($\mu\text{g g}^{-1}$; %)	Soil sampling followed by chemical analysis; ion exchange resin procedure	P
Mineralization rate	$\mu\text{g N g substrate dw}^{-1} \text{ day}^{-1}$	Tracing of ^{15}N released from control samples and from samples treated with chloroform fumigation to kill microbial cells; ion exchange resin procedures	F
Nutrient retention or loss	$\text{mg nutrient L}^{-1}$ leachate; $\mu\text{g nutrient g}^{-1}$ soil or plant sample; ^{15}N recovered (mg; %)	Measured as nutrient concentration in leachates (the higher the concentration in leachates, the lower the retention by the ecosystem) or as ^{15}N recovered in plants and soil organic matter	P
<i>Water balance</i>			
Water content	$\text{mg H}_2\text{O g dw}^{-1}$ or % $\text{H}_2\text{O dw}$	Harvest followed by measurement of fresh and dry weights	P

(Continued)

Table 1 Continued

Parameter measured	Usual units	Techniques	Emphasis
Water use efficiency (C assimilated per unit water transpired, integrated over a long period, e.g., a whole season or longer)	$\mu\text{mol CO}_2 \text{ mmol H}_2\text{O}^{-1}$; $\delta^{13}\text{C}/_{\text{‰}}$	Ratio of stable isotopes ^{13}C to ^{12}C in plant material compared with standard (PeeDee Belemnite)	P
Evapotranspiration	$\text{mg H}_2\text{O m}^{-2} \text{ min}^{-1}$	H_2O exchange measurements	F
Water potential (the more negative the water potential, the more negative the balance between absorption and transpiration)	Mpa	Pressure chamber measurements (pressure needed to expel a drop of sap out of the xylem)	F

^adw, dry weight.Source: More details can be found in [Pearcy *et al.* \(1989\)](#), [Ehleringer and Field \(1993\)](#), [Sala *et al.* \(2000\)](#), [Berg and McClaugherty \(2000\)](#), and [Hoover *et al.* \(2008\)](#).**Figure 1** Carbon assimilation processes at different scales and some methods for measuring them.

[Chapin *et al.* \(2005\)](#), NEP is the net biomass accumulation by a whole ecosystem and depends not only on NPP, but also on carbon losses due to the respiration of animals and microbes, leaching, erosion, exportation by animals, and in some cases volatilization due to fires.

At the regional scale, NPP can be largely accounted for by climatic factors, rainfall, and temperature. For example, precipitation, potential evapotranspiration, and radiation are enough to account for the net aboveground primary production (NAPP) of North American forests, deserts, and grasslands. In regions of the US with up to 1400 mm of annual rainfall, annual precipitation is enough to account for 90% of the variability in NAPP of grasslands ([Figure 4\(a\)](#)). At higher precipitation, NAPP depends more on other factors, and equations based on annual rainfall lose part of their predictive power. At the site level, variability in production seems to be accounted for by annual precipitation and soil water-holding

capacity (whc; [Figure 4\(b\)](#)). Soil whc can have a positive or negative effect depending on the precipitation value. In dry regions, major losses of soil water occur via bare soil evaporation. However, where sandy soils occur, bare soil evaporation is lower than in loamy soils because water penetrates deeper into the soil. For the same reason, surface runoff is also lower in sandy soils than in loamy soils. In more humid regions, substantial water losses occur via deep percolation, which is reduced in soils with high whc. This is known as the inverse texture hypothesis, proposed by [Noy-Meir in 1973](#).

At finer scales of analysis (e.g., paddocks and vegetation patches), more variables are needed to account for NAPP. Species composition and land-use regime become important factors, although drivers at a coarser scale are still in operation and constrain responses (e.g., irrespective of management or species composition, annual precipitation will set an upper boundary to NAPP). For instance, the NAPP of Argentine

Figure 2 Effects of 3-year environmental manipulations on tussock tundra species at different scales: (a) photosynthetic rate at 20 °C and in full sun, (b) total peak-season biomass (excluding roots), and (c) leaf nitrogen content. Treatments are control (C), nutrient addition (N), temperature increase (T), nutrient x temperature (NT), and light attenuation (L). Reproduced from Chapin III FS and Shaver GR (1996) Physiological and growth responses of arctic plants to a field experiment simulating climate change. *Ecology* 77: 822–840.

natural grasslands has been shown to decrease between 50% and more than 300% under moderate to heavy grazing, depending on regional climatic conditions. Species composition is crucial at this level; for example, NAPP tends to be higher in legume-dominated pastures than in grass-dominated ones because legume growth is much less limited by soil nitrogen availability due to their capacity for symbiotic nitrogen fixing.

Biomass production from local to global scales can also be estimated by indices obtained from remote sensing. The normalized difference vegetation index (NDVI) is tightly related to the fraction of the photosynthetically active radiation absorbed by the vegetation. This spectral index is derived from the reflectance in the red and infrared bands measured by different sensors (e.g., MODIS, AVHRR, and LandSat TM). Combined with information about incident radiation and an energy conversion factor, NDVI can be used to calculate productivity. The source of images to be used will depend on the spatial and temporal scales and resolution required for a particular study.

Trophic Transfer

Trophic transfer is defined here as the amount of biomass or energy, which is transferred from the primary producers to the herbivore-based food chain rather than directly from plants to detritivores. In this article, only the transfer from plants to herbivores will be analyzed. Two concepts are particularly relevant: consumption, or the amount of plant biomass consumed by herbivores, and net secondary productivity (NSP), or the amount of biomass/energy at the herbivore level that is available to carnivores. Both depend on the amount of available biomass (NPP), the quality of plant biomass, the kind of metabolism of the herbivores, and the linkages between herbivores and plants.

Effects of Nutrient Availability, Plant Production, and Plant Quality on Herbivore Performance

Plant nutrient quality can directly affect animal populations. Plants growing in low-nutrient sites tend to have elevated

Figure 3 Carbon pools in major ecosystem types. Soil stocks include biomass, soil organic mass, and litter. Pie diagrams indicate percentage of soil carbon in belowground biomass (gray) and in soil organic mass (white). Modified from Anderson JM (1991) The effects of climate change on decomposition processes in grassland and coniferous forests. *Ecological Applications* 3: 326–347, and Larcher W (1995) *Physiological Plant Pathology*. Berlin: Springer.

concentrations of carbon-based secondary compounds that deter consumption. In addition, low foliar concentrations of nutrients can result in either decreased or increased consumption by herbivores. In the second case, herbivores (most commonly insects) consume higher quantities of biomass in order to meet nutritional requirements, with or without reduced fitness as the final result. This effect, sometimes called the ‘nutrient dilution effect,’ is particularly true in the case of generalist herbivores, whose opportunities for coevolutionary adjustment to the chemistry of a particular plant species are slight.

Secondary chemicals in foliage seem to be more important as regulators of the types of herbivores prevailing in different ecosystems and their dietary habits than as regulators of consumption at the ecosystem level. There is evidence that herbivore biomass, consumption, and productivity are closely correlated with plant productivity across a wide range of ecosystems, such as deserts, savannas, agricultural grasslands, tropical forests, and salt marshes (Figure 5). Respiratory costs per unit production at the level of herbivores are higher for homeotherms (such as ungulates) than for heterotherms (such as insects). In forests, in which most herbivores are heterotherms, most production is allocated to wood, whereas in grasslands, in which homeotherms predominate, a much higher production is allocated to green tissue. This explains why net foliage production (that of leaves only) predicts consumption considerably better than net aboveground biomass.

Herbivore biomass and consumption increase as a power of NAPP, whereas net secondary production increases linearly

(Figure 5). This indicates that highly productive ecosystems sustain a larger level of herbivory per unit of NAPP than unproductive systems. This larger level of herbivory, however, is accompanied by a lower secondary production per unit of consumption. Because the foliage unconsumed by herbivores will flow into decomposer food webs, the relationship shown in Figure 5 between consumption by herbivores and NAPP indicates that the relative importance of the direct flow to detritus decreases as ecosystem productivity increases. However, the relative amount of litter that is actually consumed is small, even in the most productive systems.

Effects of Herbivores on Nutrient Cycling and Primary Productivity

Animal activity can affect nutrient cycling directly and indirectly. The amount of NAPP consumed by herbivores can vary from less than 10% in tropical rain forests to more than 50% in meadows (Larcher, 1995). Herbivores can short-circuit the decomposer pathway since urine and feces are much easier to decompose than plant litter. Many of them, such as ungulates, rodents, and ants, can also redistribute nutrients and create patches, and they can promote secondary compound production in plants, which may further deter grazers and may retard decomposition. Mammals, ants, and termites can play important roles in spatial distribution of nutrients at different scales, with impacts on the dynamics of the whole food web.

In many systems primary productivity increases with light grazing, then decreases, and finally decreases more or less

Figure 4 Regional- and site-level controls over net aboveground primary production (NAPP) of US grasslands, (a) Annual precipitation (APPT) is the main factor at the regional level, with $NAPP = 0.6 (APPT - 56)$ ($r^2 = 0.90$), where 0.6 represents the average water use efficiency of the community, and 56 mm year⁻¹ is the 'ineffective precipitation' (precipitation volume which is not enough to result in production). Addition of temperature and potential evapotranspiration did not improve the model, (b) Annual precipitation and soil water-holding capacity (whc) are the main factors at the site level, with $NAPP = 32 + 0.45 APPT - 352 whc + 0.95 whc APPT$; $r^2 = 0.67$. Reproduced from Sala OE, Parton WJ, Joyce LA, and Lawenroth WK (1988) Primary production of the central grassland region of the United States. *Ecology* 69: 40–45.

sharply as grazing becomes severe. This was at the heart of the herbivore optimization curve hypothesis proposed by S. J. McNaughton in the 1970s. Herbivore optimization models are still under debate, and to determine whether total (aboveground and belowground) biomass actually increases under herbivory is operationally difficult. However, supporting evidence has been found in a wide range of terrestrial ecosystems, including not only grasslands and wild and domestic ungulates but also forbs and geese, trees and mosses, and crops and birds. It is generally accepted that the highest production rates of plants occur when grazing occurs but it is

not too high. Factors like water and nutrient availability, grazing history and timing, and links with other trophic levels modulate this general response in particular systems.

Bottom-Up and Top-Down Controls of Food Chains

Bottom-up or resource control in food chains emphasizes the importance of resource availability (water and soil nutrients) for primary producers and the subsequent energy and nutrient flow through a series of trophic levels. Organisms at each trophic level are food-limited. The rationale of the opposite, or top-down, view is that organisms at the top of the food chain (e.g., top carnivores) are food-limited but those at lower trophic levels (herbivores) are alternatively predator- and food-limited. According to the Oksanen–Fretwell theory (Oksanen *et al.*, 1981) the importance of top-down control increases with primary productivity. This idea has found empirical support in naturally occurring ecosystems and has also been supported by smaller-scale manipulative experiments. For example, for invertebrate herbivory and predation on limestone grasslands through a series of experiments summarized in Figure 6 involving pesticide treatments, transplant of turves, and the use of bioassays (lettuce discs and blowfly maggots in order to evaluate the degree of herbivory and predation, respectively).

The literature contains clear examples of both bottom-up and top-down controls from various ecosystems around the world (see, for e.g., the classical book by White (1993) on bottom-up control and the recent review by Estes *et al.* (2011) on top-down control of some major ecosystem processes). Current thinking tends to see both processes as combined rather than mutually exclusive factors, operating in ecosystems, and switching in relative importance according to spatial and temporal variability in environmental drivers.

Nutrient Cycling

Nutrient Capture, Retention, and Release by Plants

A key, albeit controversial, concept in relation to nutrient cycling is that of resource use efficiency, or the relationship between a limiting resource (light, nitrogen, and water) and a biological process (photosynthesis and primary production). Nutrient use efficiency was originally defined by Vitousek (1982) as the total NPP (above- plus belowground) per unit nutrient absorbed annually. In practice, it has usually been measured as the ratio of dry mass to nutrient content in litter (Table 1), which is a good index of the nutrient economy in a stand as a whole and is based on information reasonably easy to obtain.

Major Controls Over Nutrient Cycling

The main factors underlying variations in nutrient cycling in different ecosystems are climatic factors, soil fertility, time from major disturbance events, and species composition. Nitrogen content is a strong control of productivity, carbon exchange, and composition on many ecosystems. In some cases, other macronutrients also exert strong controls (e.g., phosphorus and calcium in some tropical rain forests and grasslands, respectively).

Figure 5 (a) Net aboveground primary productivity (NAP) can predict net secondary productivity (NSP), consumption (C), and consumer biomass (B). $\log \text{NSP} = 1.10(\log \text{NAP}) - 327$, $r^2 = 0.364$; $\log C = 1.35(\log \text{NAP}) - 2.32$, $r^2 = 0.367$; $\log B = 1.52(\log \text{NAP}) - 4.79$, $r^2 = 0.367$. (b) Net foliage primary productivity (NFP) is a better predictor of consumption. $\log C = 2.04(\log \text{NFP}) - 4.80$, $r^2 = 0.594$. Units are $\text{kJ m}^{-2} \text{year}^{-1}$ except for biomass, which is kJ m^{-2} . All relationships are significant at $p < 0.0001$ (modified from McNaughton SJ, Oesterheld M, Frank DA, and Williams KJ (1989) Ecosystem-level patterns of primary productivity and herbivory in terrestrial habitats. *Nature* 341: 142–144).

Open Versus Tight Nutrient Cycles

A concept strongly linked with nutrient use is the degree of ‘tightness’ or ‘openness’ of nutrient cycling in different ecosystems. This refers to the relative importance of within-system nutrient cycling versus external inputs and outputs. Tropical forests are considered systems with tighter nutrient cycling than temperate forests because within-system nutrient recycling is more important than influx into or effluxes out of the system.

The Effects of Rainfall

Concentrations of available nutrients in the soil are relatively (although not absolutely) high in semiarid sites and decrease with increasing precipitation. Soil organic carbon tends to follow the opposite pattern, increasing with increasing rainfall. Whereas total soil nutrient content may also increase, carbon : nutrient ratios in soil increase with higher mean annual precipitation. This suggests that, as rainfall increases, rate of carbon accumulation in soils is higher than that of total nutrient accumulation due to differences in mineralization.

Changes in nutrient cycling ‘tightness’ with climatic factors are well illustrated by an analysis of soil and foliar nutrients in a rainfall gradient in Hawaii (Figure 7). As rainfall increases with altitude, there is a shift from relatively high nutrient availability to relatively high carbon gain by producers,

indicated by a decrease of leaf mass per area and leaf nitrogen concentration and an increase in lignin concentration with altitude (Figure 7(b)). A progressively depleted ^{15}N signature in both soils and vegetation in the wetter sites (Figure 9(a)) suggests that N cycling shifts from more open at the drier sites (larger turnover) to tighter (smaller losses) as precipitation increases.

The Effects of Soil Type, Land Use, and Vegetation Structure

A comparison among different types of Amazonian rain forest ecosystem, differing in soil properties and topographic positions (Table 2) illustrates how patterns of nutrient allocation depend on soil chemical properties and flooding regimes. In turn, soil properties influence nutrient supply, and flooding regimes affect nutrient uptake ability. Mixed and *guaco* forests, located in higher topographical positions, show relatively high nitrogen contents in both soil and vegetation. In the tall *caatinga* forest, the proportion of total nitrogen in living biomass is much higher than in the mixed forest and *guaco* forests, and decomposition is slower, associated with water-logging and nitrogen limitation. Nitrogen circulates in larger amounts in mixed and *guaco* forest, which show more ‘open’ nitrogen cycling than tall *caatinga* forest.

Figure 6 (a) Estimation of herbivore and carnivore activity, measured as a percentage of lettuce discs and maggots consumed, respectively, and (b) illustration of the Oksanen–Fretwell theory of interaction between trophic dynamics and primary productivity in British limestone grasslands with low (I), intermediate (II), and high (III) productivity. At very low productivity, the vegetation did not experience a detectable amount of herbivory. Vegetation of intermediate productivity supported a high level of herbivory and responded strongly to the removal of herbivores. Productivity in this situation is believed to be insufficient to sustain a high intensity of ‘top-down’ control. In the case of highly productive vegetation, carnivory was strong and the intensity of the top-down control by carnivores on plant mass removal by herbivores was maximum. Reproduced from Fraser LH and Grime JP (1997) Primary productivity and trophic dynamics investigated in a north Derbyshire, UK, dale. *Oikos* 80: 499–508.

Changes in vegetation structure due to land use can lead to different nutrient relations in sites under similar climatic and original soil conditions. A comparison between a tropical dry deciduous forest and savannas derived from the same forest and now maintained by grazing and fire in northern India (Table 3) shows that nutrient cycling is faster in the vegetation, litter, and soil of the savanna. The forest shows a higher nutrient use efficiency: Whereas the biomass and nutrient content are much higher, the annual net production and nutrient uptake are similar to those of the

savanna. In the savanna there is smaller permanent nutrient storage, and significant nutrient leakage from the system, reflected in lower soil content, indicating more open nutrient cycling.

Decomposition: From Nutrient Organic to Inorganic Forms Available to Plants

The process of decomposition, or disintegration of plant and animal residues by the soil detrital food web, is a key step in nutrient cycling. This is because it transforms nutrients already present in the system in organic form into the inorganic forms available for new plant growth. Most plants absorb nutrients in inorganic form, although some plants can incorporate organic forms of nitrogen with the intervention of mycorrhizal symbionts or through highly specialized roots. However, these cases seem mostly restricted to very nutrient-poor systems. In most ecosystems, the majority of primary production is not consumed by herbivores but is passed directly to detritus. A smaller fraction of primary production is incorporated into herbivores and carnivores, which becomes detritus when these organisms die. The ultimate end product of organic matter breakdown is inorganic forms of carbon (CO_2) and nutrients (nitrates, ammonium, and phosphates). Decomposition depends on soil environment (water potential, temperature, and aeration), microsite characteristics (slope, texture, drainage, aspect, and cover type), substrate quality, and composition of decomposer community (size and specific composition of animal and microbe assemblages and synergistic or antagonistic relationships among them).

The control of decomposition by macroclimatic parameters is very strong. Whereas mean NPP increases by a factor of approximately 20 from tundra to tropical rain forests, mean residence times of dead organic matter decrease by a factor of approximately 200. This is primarily because soil temperatures limit decomposition more than air temperatures limit production.

At a more local scale, litter quality plays an extremely important role in determining decomposition rates. The decomposability of litter from different plant species tends to be strongly correlated with the palatability of living leaves. This suggests that the same compounds that determine palatability aboveground control litter decomposition by soil microbiota. The most widely used indexes to describe litter quality are the carbon : nitrogen and lignin : nitrogen ratios, with higher ratios being associated with lower decomposition rates (Table 4).

A worldwide review of litter decomposition studies by Cornwell *et al.* (2008) found that litter decomposition rate can vary more than 18 times among species. It is also found that large differences in decomposition rate among coexisting species can be found in most major biomes of the world.

Mineralization and Immobilization of Nutrients in the Soil

The release of organically bound nutrients into the inorganic forms available to most plants is called mineralization. Because decomposer soil organisms require these nutrients to be incorporated into their bodies, decomposition can only

Figure 7 Influence of precipitation on nutrient cycling. Nitrogen cycle becomes increasingly closed with increased precipitation in Hawaii, (a) $\delta^{15}\text{N}$ average values of leaves of seven species, (b) Leaf mass per area (LMA), lignin concentration, and foliar N concentration of the dominant *Metrosideros polymorpha* Gaud. proceed if there is an adequate nutrient supply to the decomposers. Otherwise, they can act as a net sink for available nutrients in the system rather than as a net source, and decomposition is then said to be nutrient limited. The retention of nutrients by decomposers of nutrient-deficient substrates is termed 'immobilization.' Mineralization and immobilization tend to occur simultaneously in most systems; but one of them

usually predominates over the other, with important implications in the whole functioning of the system. For example, the decrease in soil fertility immediately after the addition of cereal straw to the soil is due to immobilization, with carbon: nitrogen ratios of 100 to 150:1. In arable soils, a carbon: nitrogen ratio of 20:1 is considered the threshold between net immobilization and mineralization.

Table 3 Nutrient cycling in two tropical dry deciduous vegetation types under the same climatic and soil conditions, with different land-use history in Northern India

	Dry deciduous forest			Savanna		
Production ($\text{t ha}^{-1} \text{ year}^{-1}$)		15			11	
Total biomass (t ha^{-1})		95			67	
	N	P	K	N	P	K
Nutrient uptake per unit energy captured ($\text{mg } 1000 \text{ kcal}^{-1}$)	3000	225	1720	3290	320	2740
Vegetation nutrient content (kg ha^{-1})	680	53	451	87	8	74
Litter nutrient content (kg ha^{-1})	37	3	11	14	1	11
Soil nutrient content (0–30 cm depth) (kg ha^{-1})	2906	126	377	2386	134	160
Total litter fall ($\text{kg ha}^{-1} \text{ year}^{-1}$)	80	6	38	82	8	77
Total nutrient release (leaf + root decomposition; $\text{kg ha}^{-1} \text{ year}^{-1}$)	104	8	58	124	11	107
Nutrient retention in vegetation ($\text{kg ha}^{-1} \text{ year}^{-1}$)	62	4	38	20	2	17

Litter Decomposition and Composition of Detrital Food Webs

The composition of the decomposer communities, which include macrofauna (earthworms and arthropods that carry out initial comminution, mixing, and dispersion of litter and microbial propagules), mesofauna (springtails, mites, and enchytraeid worms), and microbiota (fungi, bacteria, protozoa, nematodes, and actinomycetes), affects the local decomposition rate. Several experiments manipulating densities of bacteria, fungi, and their predators (e.g., protozoa and nematodes) as well as macrofauna (e.g., millipedes) have shown that the composition of the detrital food web is a strong factor determining the balance between net mineralization and immobilization. Belowground food webs are often connected with aboveground food webs in complex positive and negative feedbacks, with consequences at the ecosystem-level processes such as carbon sequestration and soil nutrient supply. For example, aboveground grazing by vertebrates on plants can increase microbial activity and mineralization. Further examples of the ecosystem-level consequences of the interactions between aboveground and belowground food webs can be found in the synthesis works by Wardle *et al.* (2004) and Bardgett and Wardle (2010).

Water Dynamics

Water flow through the plant compartment of the soil–plant–atmosphere continuum is regulated at the plant–air

interface, where the transition of liquid water to vapor occurs and the steepest gradient of water potential exists. The shoots are exposed to the high vapor pressure deficit of the air and a flow of water through the plant is set in motion. In this way, and depending on xylem structure, the plant component of the system bridges the steep water potential gradient between soil and air.

Vapor loss from land and vegetation is governed by leaf area, by stomatal and aerodynamic conductances of plant canopies, and by the contribution of evaporation from soils, and it affects numerous terrestrial processes ranging from the biogeochemical cycling of elements to the development of regional climate. The aerodynamic conditions above and in the canopy, determined by the density and the architecture of a vegetation stand, strongly influence transpiration. These can also affect climate, and therefore water availability, at the regional level. For example, deforestation, by reducing roughness and increasing albedo, tends to result in higher temperatures and decreased precipitation.

Much of the terrestrial evaporative water loss passes through the stomata pores of plant leaves. Given certain meteorological conditions, the strongest biotic determinants of transpiration from vegetation are stomatal opening (usually expressed as diffusive conductance of leaves for water vapor) and the amount of leaf area per land area (leaf area index; LAI). Maximum canopy conductance increases with LAI up to a point. Below an LAI of approximately three, wet soil evaporation contributes significantly to total ecosystem evaporation. Examples of vegetation types with LAI below three are

most deserts and tundra ecosystems, some temperate grasslands, and some semiarid shrubs dominated by members of the genera *Eucalyptus* or *Acacia*.

Maximum diffusive conductance of canopy plus soil and maximum photosynthetic rate tend to be correlated, with the correlation being better for herbaceous plants; woody plants tend to assimilate less carbon per unit of transpirational water loss. Evapotranspiration and carbon assimilation are so coupled that water use efficiency at the ecosystem level (how much biomass can be built up per unit of water transpired) can be approximately estimated as NPP/precipitation.

Because of the link between water loss and CO₂ absorption at the leaf level, and because it is a very important factor in soil processes, water availability can also indirectly control ecosystems by affecting cycling of carbon and nitrogen (see *Open Versus Tight Nutrient Cycles and The Effects of Rainfall*). There is evidence suggesting that the nutritional status of a canopy type determines the capacity for exchanging gases with the atmosphere. Maximum evaporation from vegetation plus soil and carbon assimilation rates have been shown to be determined by plant nutrition across very different ecosystem types. However, these patterns apply for maximum rates, which do not always reflect seasonal carbon or water balances. For example, coniferous forests are less sensitive than grasslands to soil drought. They appear to close their stomata at lower soil water content than do herbaceous plants. In addition, woody vegetations are generally deeper rooted and thus access a larger soil and water volume than do herbaceous species. Apparently, the main variable that determines seasonal carbon balance is the total length of the growing season, which depends mainly on functional rooting depth of the plants. The constraints during the growing season, rather than those during the unfavorable season, seem to determine the success of different plant life-forms in different regions of the world.

Ecosystem Functioning Under Disturbance: Resistance and Resilience

Ecosystem stability is often divided into two components: resistance and resilience. Ecosystem resistance is the ability of a system to avoid change – the capacity to stay in the same state in the face of perturbation (e.g., fire, unusual frost or drought, plowing, eutrophication). Ecosystem resilience is the rate at which a system returns to its former state after being displaced from it by a perturbation. Not all aspects of ecosystem functioning are equally resistant or resilient. The most commonly measured ones (which are not necessarily the most important or sensitive ones) are species composition and biomass. Usually, a standard or ad hoc index is constructed that relates vegetation structure or composition before the perturbation to that after the perturbation. A higher dissimilarity means the ecosystem has a lower resistance. The longer amount of time needed to achieve maximum similarity between the predisturbance and postdisturbance situation, the lower the resilience. Some authors have used indicators other than community composition, such as nutrient loss rate, to estimate stability; the higher the relative nutrient loss rate

Figure 8 Relationships between estimates of (a) drought resistance, (b) frost resistance, (c) fire resilience and nutrient stress tolerance (expressed as scores on a PCA axis) for 26 British herbaceous species. Experimental treatments of fire, drought, and frosts were applied to turves of natural herbaceous vegetation. The resistance of each species was measured as the ratio of the biomass of that species in the treated turves to its biomass in the control turves immediately after the application of the treatments. The resilience (capacity for recovery) of each species was measured as the ratio of the biomass of that species in the treated turves to its biomass in the control turves 8 weeks and 1 year after applying the treatments. Modified from MacGillivray CW, Grime JP, and the ISP Team (1995) Testing predictions of the resistance and resilience of vegetation subjected to extreme events. *Functional Ecology* 9: 640–649.

following disturbance, the lower the resistance, and the longer the time to restore 'normal' nutrient loss rate, the lower the resilience.

Evidence has accumulated for the idea that both components of ecosystem stability are primarily determined by key traits of the dominant plant species. Highly productive communities, dominated by fast-growing plants, tend to have high resilience and low resistance, with the opposite being true for communities dominated by slow-growing plants. Productivity and seed production (especially persistent seeds) favor resilience, whereas preferential allocation to storage and defense favors resistance. These ideas were formalized by Lepš *et al.* (1982) on the basis of studies of old-field successional communities. Recently, new experimental support has been provided for the idea that vegetation resistance and resilience in the face of extreme events are a function of the nutrient stress tolerance of the component species. Figure 8 illustrates that resistance to extreme events increases, and resilience decreases with increasing nutrient stress tolerance in herbaceous communities.

The size and the turnover rate of the detrital compartment also have implications for ecosystem stability. Ecosystems with high carbon:nutrient ratios in the soil are effective at immobilizing large amounts of nutrients. This immobilization can substantially control the nutrient losses as long as a sufficient amount of plant residue is left on the site to sustain the microorganisms that immobilize the nutrients in their biomass. Therefore, soil organic mass is a major determinant of ecosystem resistance. However, systems with tight nutrient cycles have increased return time to equilibrium (lower resilience). When substantial amounts of biomass are removed from these systems, causing high nutrient loss, recovery may be very slow because there is little throughflow of nutrients coming from outside the system compared with the nutrient lost. As a general rule, higher nutrient mean residence time in an ecosystem increases its resistance and decreases its resilience.

Ecosystem Functioning and Functional Diversity

Taxonomic and Functional Diversity

The most common way of assessing biodiversity is still the measurement of the number and relative abundance of species per area. Taxonomic diversity *per se* is an important parameter for conservation, but it provides little information on the magnitude and rate of ecosystem processes. However, as discussed in the section Approaches to Analysis and Measurement of Ecosystem Functioning, measurements of pools and flow rates at the whole ecosystem level provide little information about a system's conservation value or about its likely response in the face of a perturbation. An intermediate approach is the one based on plant functional types. Functional types are sets of plants sharing similar responses to environmental conditions and similar effects on major ecosystem processes. This approach is as old as ecology itself, but it has gained renewed interest in the past few years because it bridges the gap between individual species and whole-ecosystem functioning, explains particular values of pools and flow rates,

and improves predictions of how ecosystems can be modified by the introduction of new abiotic (e.g., fertilization) or biotic factors (e.g., invasion by alien species). The practical value of distinguishing discrete 'types' is obvious. However, it is important to bear in mind that most real plants represent transitions between, rather than typical examples of, different functional types. In fact, functional ecology has now moved from an emphasis on discrete types toward a focus on these recurrent suites of associated traits, also called functional syndromes. This concept reflects better the continuous nature of the trait variation that occurs in natural ecosystems. However, functional types are still indispensable for many purposes that require clear limits between target- and nontarget organisms.

Ecosystem Functioning and Biodiversity

Although the role of species richness *per se* remains controversial, and the evidence is sparse, the importance of the role of functional types, particularly the dominants, is incontestable. Until the early 1980s, studies on the relationship between diversity and ecosystem functioning usually emphasized the impacts of ecosystem processes on biodiversity. More recently the question has been reversed, and there is

Figure 9 Proposed ecosystem effects of species in different positions along an idealized dominance–diversity curve. Transients are those species unable to regenerate and persist *in situ*; their sources are soil seed bank and seed rain from the surrounding landscape. Immediate effect, control over major processes of resource dynamics; filter effect, positive or negative influence on the regeneration of dominants following major perturbations; founder effect, reservoir of potential colonizing dominant and subordinate species in the event of ecosystem reassembly. Adapted from Grime JP (1998) Benefits of plant diversity to ecosystems: Immediate, filter and founder effects. *Journal of Ecology* 86: 901–910.

much more emphasis on how diversity influences ecosystem functioning. Biodiversity has moved from the y to the x axis. Dominant species or functional types, which account for most of the standing biomass and energy flow, tend to be the most

important (and sometimes the only) components of biodiversity accounting for ecosystem functioning at the local level. This, and the fact that they tend to represent a small proportion of the local species assemblage, provides strong

Figure 10 Some of the most common associations among vegetative traits (right), among regeneration traits (left), between vegetative and regenerative traits, and between traits and major ecosystem processes. SLA, specific leaf area; LWR, leaf weight ratio; RGR, relative growth rate.

Table 5 Examples of individual plant traits which strongly influence processes of the community/ecosystems in which they are dominant

Individual trait	Ecosystem/community process
Relative growth rate	Productivity, resilience, trophic transfer
Leaf turnover rate	Nutrient cycling, detritivore diversity and biomass
Nutrient content	Nutrient cycling, trophic transfer, detritivore biomass
Life span	Resistance
Canopy structure	Aerodynamic conductance, interception, water relations, runoff, roughness/albedo, temperature buffering, soil stability, consumer biodiversity
Secondary growth	Carbon sequestration, trophic transfer, nutrient cycling
Ramification	Structural complexity, consumer biodiversity, resistance (particularly drought), temperature buffering
Root architecture	Water uptake, soil stability
Reserve organs	Resilience
Pollination mode	Expansion over landscape
Persistent seed bank	Resilience
Seed number	Expansion over landscape
Dispersal mode	Expansion over landscape

Source: Modified from Díaz S, Cabido M, and Casanoves F (1999) Functional implications of trait–environment linkages in plant communities. In: Weiher E and Keddy PA (eds.) *Ecological Assembly Rules*, pp. 338–362. Cambridge, UK: Cambridge University Press.

evidence that further studies on the role of biodiversity on ecosystem functioning should focus on them. However, the likely (but far less known) role of subordinates and even rare species in maintaining long-term ecosystem functioning, especially in the face of disturbances, has also been stressed (Figure 9).

Links Between Plant Functional Traits and Ecosystem Functioning

The existence of suites of vegetative traits consistently associated across taxa and ecosystems (e.g., plants that 'go for it' and plants that 'sit and wait') has been repeatedly documented and is increasingly accepted. Central to the plant functional type approach is the idea that life history, allocation, and phenological, physiological, architectural, and reproductive traits of dominant plant species appear to be associated in a limited number of combinations and strongly determine vegetation structure and ecosystem functioning (Figure 10). By being primary components of ecosystem-level fluxes of matter and energy, dominant plant functional types are indirect determinants of the biogeochemical cycles of carbon, water, and nutrients. Individual examples of strong links between plant traits and ecosystem processes have accumulated in the past few decades (Table 5).

Major ecosystem processes appear more strongly and directly linked to recurrent suites of vegetative traits than to

regeneration traits (Figure 10). Plant regeneration traits appear to be under the control of selective forces different from those that operate on resource dynamics during the established phase. *In situ* plant regeneration by seed is an important aspect of resilience and also strongly influences migration across the landscape in the face of climatic changes. Seed production, germination, dispersion, and establishment are therefore key aspects in determining ecosystem functioning in the face of major changes of climate and land use, although their role has proved much more difficult to document than that of adult-phase traits.

Figure 12 General characteristics of different approaches to the study of ecosystems.

Figure 13 Examples of calibration of easily measured against more time-consuming vegetative and regeneration traits, (a) Percentage leaf litter mass loss of different plant groups as a function of tensile strength of fresh leaves (reproduced from Cornelissen JHC, Pérez-Harguindeguy N, Díaz S, *et al.* (1999) Leaf structure and defence control litter decomposition rate across species, life forms and continents. *New Phytology* 143: 191–200). (b) Relationship between seed weight and shape (expressed as variance of seed dimensions) in 44 British species: ●, species with seeds that persist in the soil for at least 5 years; ○, species with seeds that persist in the soil for <0.5 years; ◇, species whose seed bank type could not be determined. The dashed line encloses the region within which all seeds examined are long lived (reproduced from Thompson K, Band SR, and Hodgson JG (1993) Seed size and shape predict persistence in soil. *Functional Ecology* 7: 236–241).

Positive-Feedback Switches

The effect of the biotic component on ecosystem dynamics often takes the form of ‘switches’ or positive-feedback processes in which members of a community modify

their environment, making it more suitable for themselves. This term was coined in 1992 by J.B. Wilson and A.D.Q. Agnew (Wilson and Agnew, 1992), who provided an extensive list of examples, some of which are shown in Figure 11.

Measurement, Analysis, and Prediction of Ecosystem Functioning: Major Protocols and Obstacles

Monitoring, Field Manipulations, and Synthesized Ecosystems: A Gradient of Questions and Methods

The understanding of how ecosystems function can be achieved by a whole gradient of protocols, from simply documenting what is happening in real systems to synthesizing model ecosystems from scratch. These extreme approaches represent a trade-off between realism and precision and between the documentation of general patterns and that of the specific mechanisms underlying them. The monitoring of real ecosystems often needs to be performed by 'soft' approaches. It is important at the initial heuristic stage and when testing whether results found in simpler experiments can be reasonably applied to the real world (synthesis stage). Experiments on synthesized ecosystems, however, are ideal for the stage of testing specific hypotheses on mechanisms that may account for the patterns observed (analytic stage). Field manipulations lay in the middle of this gradient (Figure 12).

Monitoring Real Ecosystems: Approaches Based on Functional Traits

Processes in natural ecosystems can be recorded by applying the usual methods of measuring pools and flows described previously (see Whole-Ecosystem Approaches and Approaches Based on Community Structure and Composition and Measurement of Short-Term Resource Dynamics and Long-Term, Large-Scale Ecosystem Processes). Alternatively, ecosystem functioning can be inferred from the presence and abundance of plant traits which are easily measured but at the same time have clear implications at the ecosystem level. Some examples of traits considered good indirect indicators of ecosystem processes are given in Table 5. Trait-based approaches have the advantage that they need a minimum investment in financial and technological resources and can be utilized to characterize extensive areas or high numbers of systems in a short period of time. The result is usually a comparative estimation of ecosystem functioning. This in turn needs to be calibrated against direct measurements of the plant's more direct contribution to ecosystem processes of interest, performed in a considerably smaller subset of samples. For example, leaf tensile strength correlates well with decomposition rate, which is a trait known to strongly influence nutrient cycling at the ecosystem level. The easily measured seed mass and shape correlate well with seed persistence in the soil, a trait directly involved in vegetation resilience that is considerably more difficult to measure; (Figure 13).

Experimental Manipulations Involving 'Natural' Versus Synthesized Ecosystems

The major disadvantage of field experiments is that the degree of control of independent and external variables is low compared to manipulating them. The amount of 'noise' (unwanted variance) is usually high, and enough replicates in order to reduce it are usually unavailable or involve prohibitive costs. However, synthesized ecosystems, such as microcosms, never come close to the realism of experiments involving manipulations of real ecosystems, they are always a

badly simplified version of nature, and they have severe size limitations (e.g., for ecosystems based on woody vegetation). Considering the realism–precision trade-off illustrated in Figure 12, and taking into account that some processes scale up poorly from single systems to complex ecosystems (see Whole-Ecosystem Approaches and Approaches Based on Community Structure and Composition and Measurement of Short-Term Resource Dynamics and Long-Term, Large-Scale Ecosystem Processes), field experiments are indispensable. However, microcosms work has produced highly relevant insights into ecosystem functioning, including relationships between trophic levels, community roles of symbionts, feedbacks involved in soil fertility and climate manipulation; indeed some of the most controversial and inspiring experiments on the role of biodiversity in determining ecosystem functioning have involved microcosms. Field manipulations, such as the application of treatments to real vegetation plots, or the selective removal of certain components of the community, have some limitations. These include the difficulty of separating the effects of removal of one component from the effect of the disturbance caused during the removal process and the difficulty of minimizing spatial heterogeneity that usually masks treatment effects. However, they are an excellent intermediate step between laboratory experiments and the long-term monitoring of undisturbed systems. Additionally, they have produced important evidence of the difficulties and potentialities of scaling up from individual physiology to ecosystem functioning (see Figure 2), and they will likely continue to provide fruitful insight in ecosystem ecology.

Glossary

Biological integrity Wholeness of a living system, including the capacity to sustain the full range of organisms and processes having evolved in a region.

Biosphere The thin layer of life at or near the surface of the Earth.

Biota Living things, in particular, the flora and fauna of a region.

Biotic impoverishment Systematic reduction in Earth's capacity to support life.

Ecosystem engineers Organisms that physically shape their environment, including organisms that create or modify the environments of other organisms.

Environment Surroundings; the complex of physical, chemical, and biotic factors acting upon a living system and influencing its form, function, and survival.

Health A flourishing condition, well-being; capacity for self-renewal.

Impact A forceful contact; a major effect of one thing on another.

One Species' Impact

All organisms change their environment as they live, grow, and reproduce. Over millennia, organisms evolve to contend with changes in their environment. Those that do not adapt go extinct. Those that survive are molded by evolution and biogeography as the environment changes. Even unusual or seemingly catastrophic events, like tidal waves from earthquakes, are an integral part of the ecological contexts to which organisms adapt over long time spans.

Some organisms, like beavers and elephants, change their surroundings so dramatically that they have been called ecosystem engineers. Beaver dams alter the flow of rivers, increase dissolved oxygen in downstream waters, create wetlands, and modify streamside zones. African elephants convert wooded savanna to open grassland by toppling trees as they browse. Change brought about by living things, including ecosystem engineers, has been slow and incremental in evolutionary terms. Ecosystem engineers evolve along with other inhabitants of their environments, developing ways to coexist; like other environmental components, ecosystem engineers, and their effects are part of an evolving ecological context.

In contrast, human effects since the Industrial Revolution – including many that may be invisible to a casual observer – outpace the capacity of living systems to respond. In evolutionary terms, these effects are recent and outside the experience of most organisms. Over the past two centuries – barely more than two human lifetimes – humans have profoundly altered living and nonliving systems everywhere. For the first time in the Earth's history, the environmental impact of one species, *Homo sapiens*, is the principal agent of global change. Understanding the environmental impacts of human actions is one of modern science's greatest challenges. Understanding the consequences of those impacts, and managing them to protect the well-being of human society and other life on Earth, is humanity's greatest challenge.

Human Environmental Impact Through Time

The human evolutionary line began in Africa about 7 million years ago (Ma). It took some 5 or 6 million years (My) for

protohumans to spread from Africa to Asia and then to Europe. These early humans, like other primates, made their living by seeking food and shelter from their environment, gathering plant foods, and hunting easy-to-kill prey. Sometimes, they also experienced threats from their environment, including accidents, droughts, vector-borne diseases, and attacks from predators. At this stage, with relatively low population densities and limited technologies, humans were not ecosystem engineers.

By some 50,000 years ago, however, humans had learned to use fire; developed complex tools, weapons, and language; and created art. On local scales, these modern humans were very much ecosystem engineers. Sometimes their enhanced abilities to make a living outstripped their local environment's capacity to provide that living, and they caused local ecological disruptions. On several continents, for example, humans hunted large mammals to the point where many, such as the marsupial lion of Australia, went extinct. As humans became more efficient at exploiting their local environments, they spread farther. By 13,000 years ago, modern humans had spread to all continents and many islands across the globe. Then, about 10,000 years ago, people began to domesticate plants and animals. Instead of searching for food, they began to produce food.

Food production changed the course of human and environmental history. Domestication of plants and animals enabled people to adopt a sedentary lifestyle. As detailed by geographer and ecologist Diamond (1997, 2002), populations grew as agriculture developed, because larger sedentary populations both demanded and enabled more food production. Local ecological disruptions became more numerous and widespread and more intense. With animal domestication, contagious diseases of pets and livestock adapted to new, human hosts. Diseases spread more quickly in crowded conditions; inadequate sanitation compounded the effects. From agriculture, civilization followed and with it, cities, writing, advanced technology, and political empires. In just 10,000 years, these developments led to nearly 7 billion people on Earth, industrial societies, and a global economy founded on complicated technologies and fossil fuels. Humans have emerged as ecosystem engineers on a global scale. The ecological disruptions we cause are no longer just

local or regional but global, and we have become the principal threat to the environment.

Yet despite today's advanced technologies, humans are as dependent on their environments as other organisms are. History, not just ecology, has been very clear on this point. From the Old Kingdom of Egypt more than 4000 years ago to the culture that created the huge stone monoliths on Easter Island between 1000 and AD 1550 to the 1930s Dust Bowl of North America, civilizations or ways of life have prospered and failed by using and (mostly unwittingly) abusing natural resources.

In Old Kingdom Egypt, the resource was the valley of the Nile, richly fertilized with sediment at each flooding of the river, laced with canals and side streams, blessed with a luxuriant delta. Agriculture flourished and populations swelled, until unusually severe droughts brought on the civilization's collapse. On Easter Island, the resource was trees, which gave Polynesians colonizing the island the means to build shelter, canoes for fishing the open waters around the island, and log rollers for moving the ceremonial stone monuments for which the island is famous. Deforestation not only eliminated the humans' source of wood, but also further deprived the already poor soil of nutrients and made it impossible to sustain the agriculture that had sustained the island's civilization. On the dry Great Plains of North America, settlers were convinced that rain would follow the plow, and so they plowed homestead after homestead, only to watch their homesteads' soils literally blow away in the wind.

In these cases and many others, human civilizations damaged their environments, and their actions also worsened the effects on their civilizations of climatic or other natural cycles. Yet in each case, a human culture was operating precisely the way it had evolved to operate: The culture of Old Kingdom Egypt enabled its people to prosper on the Nile's natural bounty, but prolonged, unprecedented drought brought starvation and political disorder. Easter Islanders thrived and populated the island until its resources were exhausted. Dust Bowl farmers lived out their culture's view of dominating and exploiting the land for all it was worth. The inevitable outcome for all three cases was a catastrophe for the immediate environment and the people it supported – not only because the people were unprepared to cope with dramatic natural changes in their environments but because their own actions magnified the disastrous effects of those changes.

Quoting an apt bit of cynical graffiti, historical philosopher Wright (2004, p. 107) sums up what he calls the hazards of human progress this way: "Each time history repeats itself, the price goes up." Indeed, as the second decade of the 21st century begins, humans are ecosystem engineers on a planetary scale, and our global civilization threatens the life-sustaining capacity of all of Earth's environmental "spheres":

- *Geosphere (lithosphere): Earth's crust and upper mantle, containing nonrenewable fossil fuels, minerals, and nutrients that plants require.* The activities of plants, animals, and microorganisms weather mineral soils and rocks, create organic soils, and alter erosion and sedimentation rates. Humans mine minerals, metals, and gems; extract fossil fuels including coal, oil, and natural gas; and increase erosion and sedimentation by removing or altering natural plant cover through agriculture, logging, and urbanization.

- *Atmosphere: the thin envelope of gases encircling the planet.* Living systems modify the atmosphere, its temperature, and the amount of water it contains by continually generating oxygen and consuming carbon dioxide through photosynthesis and affecting the amount and forms of other gases. Humans release toxic chemicals into the air and alter the climate by raising the atmospheric concentration of greenhouse gases, such as carbon dioxide and methane, through the burning of fossil fuels in motor vehicles, ships, airplanes, and power plants.
- *Hydrosphere: Earth's liquid surface and underground water; its polar ice caps, oceanic icebergs, and terrestrial permafrost; and its atmospheric water vapor.* Living systems alter the water cycle by modifying the Earth's temperature and the amount of water plants send into the atmosphere through a process called evapotranspiration. Humans build dams, irrigation canals, drinking-water delivery systems, and wastewater treatment plants. They use water to generate electricity; they mine groundwater from dwindling underground aquifers for farming as well as drinking; they alter the flows of surface waters for everything from transportation to the mining of gold; they drain wetlands to gain land area and abate waterborne diseases. Modern human interference in global climate is likely to disrupt the entire planetary water cycle.
- *Biosphere: the totality of Earth's living systems, that part of the Earth inhabited by living organisms.* Life on Earth emerged 3.9 billion years ago and has sustained itself through changes in form, diversity, and detail since then. No planet yet discovered supports complex life as we know it on Earth. As predators, humans have decimated or eliminated wild animal populations worldwide. As domesticators of animals and plants, humans have massively reshaped landscapes by cutting forests, burning and plowing grasslands, building cities, desertifying vast areas, and overharvesting fish and shellfish. Human actions have precipitated a spasm of extinctions that today rivals five previous mass extinctions caused by astronomical or geological forces, each of which eliminated more than 70% of species then existing.

Humans themselves may be thought of as a sphere within the greater biosphere: the *ethnosphere*, or the sum total of all thoughts and intuitions, myths and beliefs, ideas and inspirations brought into being by the human imagination since the dawn of consciousness. In the words of anthropologist Davis (2009, p. 2), who coined and defined the term in 2002, "The ethnosphere is humanity's greatest legacy. It is the product of our dreams, the embodiment of our hopes, the symbol of all we are and all that we, as a wildly inquisitive and astonishingly adaptive species, have created." But, Davis notes, just as the biosphere is being severely eroded, so too is the ethnosphere, but at a much faster pace.

Today, the scientific consensus is that *H. sapiens* – a single species – rivals astronomical and geological forces in its impact on life on Earth.

Biotic Impoverishment

The first step in dealing with the present impact of human activity is to correctly identify the nature of humanity's

relationship with the environment and how human actions affect that relationship. Many people still see the environment as something people must overcome, or they regard environmental needs as something that ought to be balanced against human needs (for example, jobs vs. the environment). Most people still regard the environment as a provider of commodities or a receptacle for waste.

When asked to name humanity's primary environmental challenges, people typically think of running out of non-renewable raw materials and energy or about water and air pollution. Environmental research and development institutions focus on ways technology can help solve each problem, such as fuel cells to provide clean, potentially renewable energy or scrubbers to curb smokestack pollution. Even when people worry about biodiversity loss, they are concerned primarily with stopping the extinction of species, rather than with understanding the underlying losses leading up to species extinctions or the broader biological crisis that extinctions signal.

These perspectives miss a crucial point: the reason pollution, energy use, extinction, and dozens of other human impacts are important is their larger impact on the biosphere. Ecosystems, particularly their living components, have always provided the capital to fuel human economies. When populations were small, humans making a living from nature's wealth caused no more disruption than other species. But with nearly 7 billion people occupying or using resources from every place on Earth, humans are overwhelming the ability of other life-forms to make a living and depleting the planet's natural wealth. At this point in the planet's history, one species is compromising Earth's ability to support the living systems that evolved here over millions of years. The systematic reduction in Earth's capacity to support life – which Woodwell (1990) termed 'biotic impoverishment' – is thus the most important human-caused environmental impact. At best, the ethics of this impact are questionable; at worst, it is jeopardizing our own survival.

The connection between biotic impoverishment and extinction is intuitively obvious. By overharvesting fish, overcutting forests, overgrazing grasslands, or paving over land for cities, we are clearly killing other organisms outright or eliminating their habitats, thereby driving species to extinction and impoverishing the diversity of life. But biotic impoverishment takes many forms besides extinction. It encompasses three categories of human impacts on the biosphere: (1) indirect depletion of living systems through alterations in physical and chemical systems, (2) direct depletion of nonhuman life, and (3) direct degradation of human life (Table 1). Identifying and understanding the biological significance of our actions – their effects on living systems, including our own social and economic systems – is the key to developing effective ways to manage our impacts.

Indirect Biotic Depletion

Humans affect virtually all the physical and chemical systems life depends on: water, soils, air, and the biogeochemical cycles linking them. Some human-driven physical and chemical changes have no repercussions on the biota; others do, becoming agents of biotic impoverishment.

Table 1 The many faces of biotic impoverishment

Indirect depletion of living systems through alterations in physical and chemical systems

1. Degradation of water (redirected flows, depletion of surface and ground water, wetland drainage, organic enrichment, destruction, and alteration of aquatic biota)
2. Soil depletion (destruction of soil structure, erosion, salinization, desertification, acidification, nutrient leaching, destruction, and alteration of soil biota)
3. Chemical contamination (land, air, and water pollution from pesticides, herbicides, heavy metals, and toxic synthetic chemicals; atmospheric ozone depletion; ocean acidification; fish kills; extinctions; biotic homogenization, and biodiversity loss; bioaccumulation; hormone disruption; immunological deficiencies, reproductive and developmental anomalies; respiratory diseases; intergenerational effects)
4. Altered biogeochemical cycles (alteration of the water cycle; nutrient enrichment; acid rain; fossil fuel combustion; particulate pollution; degradation of land and water biota; outbreaks of pests, pathogens, and red tides)
5. Global climate change (rising greenhouse gas concentrations, altered precipitation and airflow patterns, rising temperatures, effects on individual and community health, shifts among and within global ecosystems)

Direct depletion of nonhuman life

1. Overharvest of renewable resources such as fish and timber (depleted populations, extinctions, altered food webs)
2. Habitat fragmentation and destruction (extinctions, biotic homogenization, emerging and reemerging pests and pathogens, loss of landscape mosaics and connectivity)
3. Biotic homogenization (extinctions and invasions)
4. Genetic engineering (homogenization of crops, antibiotic resistance, potential extinctions and invasions if genes escape, other unknown ecological effects)

Direct degradation of human life

1. Emerging and reemerging diseases (occupational hazards, asthma and other respiratory ills, pandemics, Ebola, AIDS, hantavirus, tuberculosis, Lyme disease, West Nile fever, antibiotic resistance, diseases of overnutrition, higher death rates)
2. Loss of cultural diversity (genocide, ethnic cleansing, loss of cultural and linguistic diversity, loss of knowledge)
3. Reduced quality of life (malnutrition and starvation, failure to thrive, poverty, environmental refugees)
4. Environmental injustice (environmental discrimination and racism; economic exploitation; growing gaps between rich and poor individuals, segments of society, and nations; gender inequities; trampling of the environmental and economic rights of future generations)
5. Political instability (civil violence, especially under intransigent regimes; resource wars; international terrorism; increased number of environmental refugees)
6. Cumulative effects (environmental surprises, increased frequency of catastrophic natural events, boom-and-bust cycles, interactions between disease and biodiversity, collapse of civilizations)

Degradation of Water

Humans probably spend more energy, money, and time trying to control the movement and availability of water than to manage any other natural resource. In the process, we contaminate water, move water across and out of natural basins, deplete surface and groundwater; modify the timing and amount of flow in rivers, straighten or build dikes to

constrain rivers, and alter natural flood patterns. We change the amount, timing, and chemistry of fresh water reaching coastal regions, and we dry up wetlands, lakes, and inland seas. Our demands are outrunning supplies of this non-renewable resource, and the scale of our transformations risks altering the planetary water cycle.

Physical alterations of the Earth's waters, combined with massive industrial, agricultural, and residential pollution, have taken a heavy toll on nonhuman aquatic life. By 2005 as much as one-fifth of the world's coral reefs had been destroyed, and only 30% remained healthy. Globally, the number of oceanic dead zones, where little or no dissolved oxygen exists, tripled during the last 30 years of the 20th century. The biota of freshwater systems has fared no better. A 4-year survey of the freshwater fishes inhabiting Malaysian rivers in the late 1980s found only 46% of 266 known Malaysian species. Some 40% of North America's freshwater fishes are at risk of extinction; two-thirds of freshwater mussels and crayfishes and one-third of amphibians that depend on aquatic habitats in the United States are rare or imperiled.

Humans use at least 54% of the Earth's accessible water runoff, a figure that is likely to grow to 70% by 2025. By then, more than a third of the world's population could suffer shortages of fresh water for drinking and irrigation. Groundwater aquifers in many of the world's most important crop-producing regions are being drained faster than they can be replenished: a study published in 2010 found that the rate of groundwater depletion worldwide had more than doubled from 1960 to 2000. Natural flood regimes, as in the Nile River basin, no longer spread nutrient-rich silt across floodplains to nourish agriculture; indeed, the High Dam at Aswan traps so much silt behind it that the Nile delta, essential to Egypt's present-day economy, is slumping into the sea. Whole inland seas, such as the Aral Sea in Uzbekistan, are drying up because the streams feeding them contain so little water. In addition to eliminating habitat for resident organisms, the sea's drying is bringing diseases to surrounding human populations. Indeed, diseases caused by waterborne pathogens are making a comeback even in industrialized nations.

In the past five or six decades, the number of large dams on the world's rivers grew more than seven times, to more than 40,000 today. The mammoth Three Gorges Dam across China's Yangtze River, completed in 2006, created a 660-km-long serpentine lake behind it. The dam displaced more than 1 million people and may force the relocation of another 4 million from the reservoir region, which, at 58,000 km², is larger than Switzerland. The dam has greatly altered ecosystems on the Yangtze's middle reaches, compounding perils already faced by prized and endemic fish and aquatic mammals. The sheer weight of the water and silt behind the concrete dam raises the risk of landslides and strains the region's geological structure, while water released from the dam eats away at downstream banks and scours the bottom. And by slowing the flow of the Yangtze and nearby tributaries, the dam drains the river's ability to flush out and detoxify pollutants from upstream industries.

Soil Depletion

Not just dirt, soil is a living system that makes it possible for raw elements from air, water, and bedrock to be physically and

chemically assembled, disassembled, and reassembled with the aid of living macro- and microorganisms into the green cloak of life above ground. Accumulated over thousands of years, soil cannot be renewed in any time frame useful to humans alive today, or even to their great-grandchildren.

Humans degrade soils when they compact it, erode it, disrupt its organic and inorganic structure, turn it too salty for life, and cause desertification. Urbanization, logging, mining, overgrazing, alterations in soil moisture, air pollution, fires, chemical pollution, and leaching out of minerals all damage or destroy soils. Thanks to removal of vegetative cover, mining, agriculture, and other activities, the world's topsoils are eroded by wind and water ten to hundreds of times faster than they are renewed (at roughly 10 tons ha⁻¹ year⁻¹).

Soils constitute the foundation of human agriculture, yet agriculture, including livestock raising, is the worst culprit in degrading soils. Agricultural practices have eroded or degraded more than 40% of present cropland. Over the last half century, some 24,000 villages in northern and western China have been overrun by the drifting sands of desertification. Besides topsoil erosion, the damage includes salting and saturation of poorly managed irrigated lands; compaction by heavy machinery and the hooves of livestock; and pollution from excessive fertilizers, animal wastes, and pesticides.

Living, dead, and decomposing organic matter is the key to soil structure and fertility. Soil depleted of organic matter is less permeable to water and air and thus less able to support either aboveground plants or soil organisms. The linkages between soil's inorganic components and the soil biota – naturalist Wilson's (1987) "little things that run the world" – are what give soil its life-sustaining capacity. A clear-cut forest patch whose soil biota has been damaged beyond recovery can no longer sustain trees, no matter how many are planted; another clear-cut patch whose soil community is intact – especially the close associations among fungi and tree roots – will support new tree growth. Destroying soil biota unleashes a whole series of impoverishing biotic effects both below and above ground.

Chemical Contamination

In 1962, Rachel Carson's landmark book, *Silent Spring*, alerted the world to the pervasiveness of synthetic chemicals produced since World War II. As many as 100,000 synthetic chemicals are in use today. True to one company's slogan, many of these have brought "better living through chemistry," providing new fabrics and lighter manufacturing materials, antibiotics, and life-saving drugs.

But industrial nations have carelessly pumped chemicals into every medium. Chemicals – as varied as prescription drugs flowing out of sewage plants, pesticides, heavy metals, and cancer-causing by-products of countless manufacturing processes – now lace the world's water, soil, and air and the bodies of all living things, including humans. Chemicals directly poison organisms; they accumulate in physical surroundings and are passed through and, in many cases, concentrated within portions of the food web. Chemicals cause cancer, interfere with hormonal systems, provoke asthma, and impair the functioning of immune systems. They have intergenerational effects, such as intellectual impairment in children whose mothers have eaten contaminated fish.

What's more, over half a century of pesticide and antibiotic overuse has bred resistance to these chemicals among insects, plants, and microbes, giving rise to new and reemerging scourges.

Many chemicals travel oceanic and atmospheric currents to sites far from their source. Sulfur emissions from the US Midwest, for example, fall to earth again as acid rain in Europe, killing forests and so acidifying streams and lakes that they, too, effectively die. China's burning of soft coal sends air pollution all the way to northwestern North America; the heavy haze hanging over China's chief farming regions may be cutting agricultural production by a third. Chlorofluorocarbons (CFCs), once widely used as refrigerants, have damaged the atmospheric ozone layer, which moderates how much ultraviolet radiation reaches the Earth, and opened ozone holes over the Arctic and Antarctic.

But even more alarming is an unprecedented acidification of the oceans that has only recently attracted the attention of major scientific research consortiums. Acid added to the world ocean by human activity has lowered the ocean's pH; it is lower now than it has been in 20 My, which translates into a 30% increase in sea-surface acidity since industrialization began. The future of marine life in an ocean acidifying at this speed and intensity looks bleak. As the concentration of hydrogen ions rises, the calcium carbonate in the shells or skeletons of organisms such as tropical corals, microscopic foraminifera, and mollusks begins to dissolve; further, more hydrogen ions combine with the calcium carbonate building blocks the organisms need, making it harder for them to extract this compound from the water and build their shells in the first place.

Although many of the most obviously deadly chemicals were banned in the 1970s, they continue to impoverish the biosphere. Polychlorinated biphenyls – stable, nonflammable compounds once used in electrical transformers and many other industrial and household applications – remain in the environment for long periods, cycling among air, water, and soils and persisting in the food web. They are found in polar bears and arctic villagers; they are implicated in reproductive disorders, particularly in such animals as marine mammals, whose long lives, thick fat layers where chemicals concentrate, and position as top predators make them especially vulnerable.

The agricultural pesticide DDT, sprayed with abandon in the 1940s and 1950s, even directly on children, had severely thinned wild birds' eggshells by the time it was banned in the United States. Populations of birds such as the brown pelican and bald eagle had dropped precipitously by the 1970s, although they have recovered enough for the species to be taken off the US endangered species list, the bald eagle in 2007 and the brown pelican in 2009. Reproduction of central California populations of the California condor, in contrast, continues to be threatened by DDT breakdown products, which, 40 years after the pesticide was banned, are still found in the sea lion carcasses the birds sometimes feed on.

Carson's book revealed the real danger of chemical pollutants: they have not simply perturbed the chemistry of water, soil, and air but harmed the biosphere as well. The list of chemicals' effects on living things is so long that chemical pollution equals humans' environmental impact in

most people's minds, yet it is just one form of biotic impoverishment.

Altered Biogeochemical Cycles

All the substances found in living things – such as water, carbon, nitrogen, phosphorus, and sulfur – cycle through ecosystems in biogeochemical cycles. Human activities modify or have the potential to modify all these cycles. Sometimes the results stem from changing the amount or the precise chemistry of the cycled substance; in other cases, humans change biogeochemical cycles by changing the biota itself.

Freshwater use, dams, and other engineering ventures affect the amount and rate of river flow to the oceans and increase evaporation rates, directly affecting the water cycle and indirectly impoverishing aquatic life. Direct human modifications of living systems also alter the water cycle. In South Africa, European settlers supplemented the treeless native scrub, or fynbos, with such trees as pines and Australian acacias from similar Mediterranean climates. But because these trees are larger and thirstier than the native scrub, regional water tables have fallen sharply.

Human activity has disrupted the global nitrogen cycle by greatly increasing the amount of nitrogen fixed from the atmosphere (combined into compounds usable by living things). The increase comes mostly from deliberate addition of nitrogen to soils as fertilizer but also as a by-product of the burning of fossil fuels. Agriculture, livestock raising, and residential yard maintenance chronically add tons of excess nutrients, including nitrogen and phosphorus, to soils and water.

The additions are often invisible; their biological impacts are often dramatic. Increased nutrients in coastal waters, for example, trigger blooms of toxic dinoflagellates – the algae that cause red tides, fish kills, and tumors and other diseases in varied sea creatures. When huge blooms of algae die, they fall to the seafloor, where their decomposition so robs the water of oxygen that fish and other marine organisms can no longer live there. With nitrogen concentrations in the Mississippi River two to three times as high as they were 50 years ago, a gigantic dead zone forms in the Gulf of Mexico every summer; in summer 2010 this dead zone covered 20,000 km².

The burning of fossil fuels is transforming the carbon cycle, primarily by raising the atmospheric concentration of carbon dioxide. With other greenhouse gases, such as methane and oxides of nitrogen, carbon dioxide helps keep Earth's surface at a livable temperature and drives plant photosynthesis, but since the Industrial Revolution, atmospheric carbon dioxide concentrations have risen nearly 40% and are now widely thought to be disrupting the planet's climate. In addition, the effects of catastrophic oil spills like the one that followed the April 2010 explosion of the Deepwater Horizon drilling rig in the Gulf of Mexico – and the effects of the chemicals used to disperse the resulting plumes of oil – may reverberate for decades.

Global Climate Change

In its 2007 report, written and reviewed by more than 3500 scientists, the Intergovernmental Panel on Climate Change (IPCC) concluded that climate warming was "unequivocal" (p. 2), that most of the average global warming over the previous 50 years was "very likely due to anthropogenic GHG

[greenhouse gas] increases" (p. 5), and that this warming has likely had "a discernible influence at the global scale on observed changes in many physical and biological systems" (p. 6).

The concentrations of heat-trapping gases in the atmosphere are at their highest level in more than 200,000 years. The 20th century in the Northern Hemisphere was the warmest of the past millennium; the first decade of the 21st century, and the first 7 months of 2010, were the warmest on record.

Higher global temperatures set in motion a whole series of effects, making the study of climate change, and of humans' role in it, complex and controversial. Spring arrives at least 1 week earlier in the Northern Hemisphere. Polar glaciers and ice sheets are receding. The Arctic is warming twice as fast as the rest of the planet, and arctic sea ice melted at a near-record pace in 2010. With the sun heating the newly open water, winter refreezing will take longer, and the resulting thinner ice will melt more easily the following summer.

The large-scale circulation of global air masses is changing and, with them, the large-scale cycles in ocean currents, including the periodic warming and cooling in the tropical Pacific Ocean known as El Niño and La Niña. As a result, the distribution, timing, and amount of rain and snow are also changing, making the weather seem more unpredictable than ever. Unusually warm or cold winters, massive hurricanes like those that devastated the US Gulf Coast in 2005, and weather-related damage to human life and property are all predicted to increase with global warming. In the United States in 2005, weather-related damage totaled nearly \$97 billion.

Where other nutrients are not limiting, rising carbon dioxide concentrations may enhance plant photosynthesis and growth. Rising temperatures may shift the ranges of many plants and animals – both wild and domestic – rearranging the composition and distribution of the world's biomes, as well as those of agricultural systems. The resulting displacements will have far-reaching implications not only for the displaced plants and animals but also for the goods and services humans depend on from these living systems.

Direct Depletion of Nonhuman Life

From their beginnings as hunter-gatherers, humans have become highly efficient, machine-aided ecosystem engineers and predators. We transform the land so it produces what we need or want; we harvest the oceans in addition to reaping our own fields; we cover the land, even agricultural land, with sprawling cities. All these activities directly affect the ability of other life-forms to survive and reproduce. We deplete nonhuman life by eliminating some forms and favoring others; the result is a loss of genetic, population, and species diversity.

We are irreversibly homogenizing life on Earth, in effect exercising an unnatural selection that is erasing the diversity generated by millions of years of evolution by natural selection. One species is now determining which other species will survive, reproduce, and thereby contribute the raw material for future evolution.

Overharvest of Renewable Resources

In the 1930s, so many sardines were scooped from the waters off Monterey's Cannery Row in California that the population

collapsed, taking other sea creatures and human livelihoods with it; after rebounding somewhat in the first decade of the 2000s, the species has still not recovered fully. According to the US National Marine Fisheries Service, nearly 80% of commercially valuable fish of known status were overfished or fished to their full potential by 1993. Atlantic commercial fish species at their lowest levels in history include tuna, marlin, cod, and swordfish. Overfishing not only depletes target species but restructures entire marine food webs.

Marine mammals, including whales, seals, sea lions, manatees, and sea otters, were so badly depleted by human hunters that one species, Steller's sea cow (*Hydrodamalis gigas*), went extinct; many other species almost disappeared. In the 19th century, Russian fur traders wiped out sea otters (*Enhydra lutris*) along the central California coast. With the otters gone, their principal prey, purple sea urchins (*Strongylocentrotus purpuratus*), overran the offshore forests of giant kelp (*Macrocystis pyrifera*), decimating the kelp fronds and the habitat they provided for countless other marine creatures, including commercially harvested fishes. Thanks to five decades of protection, marine mammal populations began slowly recovering – only to face food shortages as regional marine food webs continue to unravel because of fishing, changing oceanic conditions, and contamination.

Timber harvest has stripped vegetation from the Amazonian rainforest to mountainsides on all continents, diminishing and fragmenting habitat for innumerable forest and stream organisms, eroding soils, worsening floods, and contributing significantly to global carbon dioxide emissions. In the Northern Hemisphere, 10% or less remains of old-growth temperate rainforests. The uniform stands of trees usually replanted after logging do not replace the diversity lost with the native forest, any more than monocultures of corn replace the diversity within native tallgrass prairies.

Habitat Fragmentation and Destruction

A great deal of human ecosystem engineering not only alters or damages the habitats of other living things but often destroys those habitats. Satellite-mounted remote-sensing instruments have revealed transformations of terrestrial landscapes on a scale unimaginable in centuries past. Together, cropland and pastures occupy 40% of Earth's land surface. Estimates of the share of land wholly transformed or degraded by humans hover around 50%. Our roads, farms, cities, feedlots, and ranches either fragment or destroy the habitats of most large carnivorous mammals. Mining and oil drilling damage the soil, remove vegetation, and pollute marine areas. Grazing compacts soil and sends silt and manure into streams, where they harm stream life.

Landscapes that have not been entirely converted to human use have been cut into fragments. In *Song of the Dodo*, writer Quammen (1996) likens our actions to starting with a fine Persian carpet and then slicing it neatly into 36 equal pieces; even if we had the same square footage, we would not have 36 nice Persian rugs – only ragged, nonfunctional fragments. And in fact, we do not even have the original square footage because we have destroyed an enormous fraction of it.

Such habitat destruction is not limited to terrestrial environments. Human channelization of rivers may remove whole segments of riverbed. In the Kissimmee River of the US

state of Florida, for example, channelization in the 1960s transformed 165 km of free-flowing river into 90 km of canal, effectively removing 35 km of river channel and drastically altering the orphaned river meanders left behind.

Wetlands worldwide continue to disappear, drained to create shoreline communities for people and filled to increase cropland. The lower 48 United States lost 53% of their wetlands between the 1700s and mid-1980s. Such losses destroy major fish and shellfish nurseries, natural flood and pollution control, and habitat for countless plants and animals.

The mosaic of habitats in, on, or near the seafloor – home to 98% of all marine species – is also being decimated. Like clear-cutting of an old-growth forest, the use of large, heavy trawls dragged along the sea bottom to catch groundfish and other species flattens and simplifies complex, structured habitats such as gravels, coral reefs, crevices, and boulders and drastically reduces biodiversity. Studies reported on by the National Research Council of the US National Academy of Sciences have shown that a single tow can injure or destroy upward of two-thirds of certain bottom-dwelling species, which may still not have recovered after a year or more of no trawling.

Habitat fragmentation and destruction, whether on land or in freshwater and marine environments, may lead directly to extinction or isolate organisms in ways that make them extremely vulnerable to natural disturbances, climate change, or further human disturbance.

Biotic Homogenization

“The one process ongoing ... that will take millions of years to correct,” Wilson (1994, p. 355) admonishes us, “is the loss of genetic and species diversity by the destruction of natural habitats. This is the folly our descendants are least likely to forgive us.” Both deliberately and unwittingly, humans are rearranging Earth’s living components, reducing diversity and homogenizing biotas around the world. The present, continuing loss of genetic diversity, of populations, and of species vastly exceeds background rates. At the same time, our global economy is transporting species worldwide at unprecedented scales.

The globe is now experiencing its sixth mass extinction, the largest since the dinosaurs vanished 65 Ma; present extinction rates are thought to be on the order of 100–1000 times those before people dominated Earth. According to the Millennium Ecosystem Assessment, a 5-year project begun in 2001 to assess the world’s ecosystems, an estimated 10–15% of the world’s species will be committed to extinction over the next 30 years. Approximately 20% of all vertebrates, including 33% of sharks and rays, are at risk of extinction.

At least one of every eight plant species is also threatened with extinction. Although mammals and birds typically receive the most attention, massive extinctions of plants, which form the basis of the biosphere’s food webs, undermine life-support foundations. The mutualistic relationships between animals and plants, particularly evident in tropical forests, mean that extinctions in one group have cascading effects in other groups. Plants reliant on animals for pollination or seed dispersal, for example, are themselves threatened by the extinction of the animal species they depend on. Not surprisingly, some scientists view extinction as the worst

biological tragedy, but extinction is just another symptom of global biotic impoverishment.

Ever since they began to spread over the globe, people have transported other organisms with them, sometimes for food, sometimes for aesthetic reasons, and most often inadvertently. With the mobility of modern societies and today’s especially speedy globalization of trade, the introduction of alien species has reached epidemic proportions, causing some scientists to label it biological pollution.

Aliens – zebra mussels (*Dreissena polymorpha*) and tamarisks, or saltcedar (*Tamarix* spp.), in North America; the Red Sea sea jelly *Rhopilema nomadica* and the common aquarium alga *Caulerpa taxifolia* now choking the Mediterranean Sea; and Leidy’s comb jelly (*Mnemiopsis leidyi*) of northeastern America in the Black Sea, to name just a few – are present everywhere, and they usually thrive and spread at the expense of native species. On many islands, for example, more than half the plant species are not native, and in many continental areas the figure reaches 20% or more.

The costs of such invasions, in both economic and ecological terms, are high. In the United States, for example, annual economic losses due to damage by invasive species or the costs of controlling them exceed \$137 billion per year – \$40 billion more than the nation’s losses from weather-related damage in 2005. Furthermore, alien invasions cause extinctions and, when added to other extinctions and the deliberate monocultures of agricultural crops, homogenize biotas still more. Introduced species are fast catching up with habitat fragmentation and destruction as the major engines of ecological deterioration.

Genetic Engineering

Humans have been manipulating their crop plants and domesticated animals for 10,000 years or so – selecting seeds or individuals and breeding and cross-breeding them. The goal was something better, bigger, tastier, hardier, or all of the above; success was sometimes elusive, but the result was crop homogenization. Of the myriad strains of potatoes domesticated by South American cultures, for example, only one was accepted and cultivated when potatoes first made it to Europe. The new crop made it possible to feed more people from an equivalent area of land and initially staved off malnutrition. But the strain succumbed to a fungal potato blight in the 1800s. Had more than one strain been cultivated, the tragic Irish potato famines might have been averted.

In the last few decades of the 20th century, people began to manipulate genes directly using the tools of molecular biotechnology, even cloning sheep and cows from adult body cells. US farmers routinely plant their fields with corn whose genetic material incorporates a bacterial gene resistant to certain pathogens. More than 40 genetically altered crops have been approved for sale to US farmers since 1992, with genes borrowed from bacteria, viruses, and insects. The United States accounts for nearly two-thirds of biotechnology crops planted globally. Worldwide in 2003, 67.6 million hectares in 18 countries on six continents were planted with genetically modified crops, as compared with 1.7 million hectares in six countries in 1996 – a 40-fold expansion in 8 years.

Biotechnologists focus on the potential of this new-millennium green revolution to feed the growing world

population, which has added almost 1 billion people in the past decade alone. But other scientists worry about unknown human and ecological health risks; these concerns have stirred deep scientific and public debate, especially in Europe, akin to the debate over pesticides in Rachel Carson's time.

One worrisome practice is plant genetic engineers' technique of attaching the genes they want to introduce into plants to an antibiotic-resistant gene. They can then easily select plants that have acquired the desired genes by treating them with the antibiotic, which kills any nonresistant plants. Critics worry that the antibiotic-resistant genes could spread to human pathogens and worsen an already growing antibiotic-resistance problem. Another concern arises from allergies humans might have or develop in response to genetically modified foods.

Although supporters of genetic engineering believe that genetically altered crops pose few ecological risks, ecologists have raised a variety of concerns. Studies in the late 1990s indicated that pollen from genetically engineered Bt corn can kill monarch butterfly caterpillars. Bt is a strain of bacterium that has been used since the 1980s as a pesticidal spray; its genes have also been inserted directly into corn and other crops. Ecologists have long worried that genetically engineered plants could escape from fields and cross-breed with wild relatives. Studies in radishes, sorghum, canola, and sunflowers found that genes from an engineered plant could jump to wild relatives through interbreeding. The fear is that a gene conferring insect or herbicide resistance might spread through wild plants, creating invasive superweeds that could potentially lower crop yields and further disturb natural ecosystems.

In fact, herbicide-resistant turf grass tested in Oregon in 2006 did escape and spread, and transgenic canola has been appearing throughout the US state of North Dakota, which has tens of thousands of hectares in conventional and genetically modified canola. According to the scientists who discovered the transgenic escapees growing in North Dakota – far from any canola field – the plants are likely to be cross-pollinating in the wild and swapping introduced genes; the plants' novel gene combinations indicate that the transgenic traits are stable and evolving outside of cultivation.

Genetically engineered crops do confer some economic and environmental benefits: for farmers, higher yields, lower costs, savings in management time and gains in flexibility; for the environment, indirect benefits from using fewer pesticides and herbicides. But it is still an open question whether such benefits outweigh the potential ecological risks or whether the public will embrace having genetically modified foods as staples in their diet.

Direct Degradation of Human Life

Human biotic impacts are not confined to other species; human cultures themselves have suffered from the widening circles of indirect and direct effects humans have imposed on the rest of nature. Over the past hundred years, human technology has cut both ways with regard to public health. Wonder drugs controlled common pathogens at the same time that natural selection strengthened those pathogens' ability to resist the drugs. Reservoirs in the tropics made water supplies

more reliable for humans but also created ideal environments for human parasites. Industrialization exposed human society to a remarkable array of toxic substances.

Although man's inhumanity to man has been both fact and the subject of discourse for thousands of years, the discussions have mostly been removed from any environmental context. Few people today regard social ills as environmental impacts or humans as part of a biota. But diminished societal well-being – whether manifest in high death rates or poor quality of life – shares many of its roots with diminished nonhuman life as a form of biotic impoverishment.

Emerging and Reemerging Diseases

The intersection of the environment and human health is the core of the discipline known as environmental health. Among the environmental challenges to public health are the direct effects of toxic chemicals; occupational health threats, including exposures to hazardous materials on the job; and sanitation and disposal of hazardous wastes.

Exploitation of nonrenewable natural resources – including coal mining, rock quarrying or other mining operations, and petroleum extraction and refining – often chronically impairs workers' health and shortens their lives. Farmworkers around the world suffer long-term ills from high exposures to pesticides and herbicides. Partly because of increased air pollution, asthma rates are rising, particularly in big cities. Synthetic volatile solvents are used in products from shoes to semiconductors, producing lung diseases and toxic wastes. Nuclear weapons production starting in World War II, and associated contamination, have been linked to a variety of illnesses, including syndromes neither recognized nor understood at the time and whose causes were not diagnosed until decades afterward. The grayish metal beryllium, for example, was used in weapons production and was found decades later to scar the lungs of workers and people living near toxic waste sites.

Infectious diseases have challenged human populations throughout history, playing a significant role in their evolution and cultural development over the past 10,000 years, with 75% of human diseases linked to wildlife or domestic animals. The 20th century brought major successes in eradicating such infectious diseases as smallpox, polio, and many waterborne illnesses. But toward the century's end, emerging and reemerging diseases were again reaching pandemic proportions.

Infectious diseases thought to be on the wane – including tuberculosis, malaria, cholera, diphtheria, leptospirosis, encephalitis, and dengue fever – have begun a resurgence. In addition, seemingly new scourges – Ebola virus, hantavirus, HIV/AIDS, Lyme disease, and West Nile fever – are also spreading, often, it appears, from wild animal hosts to humans as people encroach further upon previously undisturbed regions. A number of studies over the decade before 2010 show complex connections between biodiversity and disease: biodiversity loss often increases disease transmission, as in Lyme disease and West Nile fever, but diverse ecosystems also serve as sources of pathogens. Overall, however, the studies indicate that preserving intact ecosystems and their endemic biodiversity often reduces the prevalence of infectious diseases.

Human migrations – including their modern incarnation through air travel – also accelerate pathogen traffic and launch global pandemics, such as the 2003 outbreak of severe acute respiratory syndrome and the 2009 swine flu outbreak caused by the H1N1 virus. Even something as simple and apparently benign as lighting can become an indirect agent of disease. Artificial lighting, especially in the tropics, for example, can alter human and insect behavior in ways that speed transmission of insect-borne diseases, such as Chagas's disease, malaria, and leishmaniasis.

In addition, especially in highly developed countries such as the United States, diseases of affluence and overconsumption are taking a toll. Heart disease is the number one cause of death in the United States; overnutrition, obesity, and diabetes due to sedentary, technology-driven lifestyles, particularly among children, are chronic and rising. One estimate put the share of US children considered overweight or obese at one in three. This rise in obesity rates has been stunningly rapid. As recently as 1980, just 15% of adults were obese; by 2008 the rate had hit 34%, and two-thirds of Americans are now considered either overweight or obese.

Loss of Cultural Diversity

Although not conventionally regarded as elements of biodiversity, human languages, customs, agricultural systems, technologies, and political systems have evolved out of specific regional environments. Like other organisms' adaptive traits and behaviors, these elements of human culture constitute unique natural histories adapted, like any natural history, to the biogeographical context in which they arose. Yet modern technology, transportation, and trade have pushed the world into a globalized culture, thereby reducing human biological and cultural diversity.

Linguists, for example, are predicting that at least half of the 7000 languages spoken today will become extinct in the 21st century. With the spread of Euro-American culture, unique indigenous human cultures, with their knowledge of local medicines and geographically specialized economies, are disappearing even more rapidly than the natural systems that nurtured them. This loss of human biodiversity is in every way as troubling as the loss of nonhuman biodiversity.

Reduced Quality of Life

The effects of environmental degradation on human quality of life are another symptom of biotic impoverishment. Food availability, which depends on environmental conditions, is a basic determinant of quality of life. Yet according to the World Health Organization, nearly half the world's population suffers from one of two forms of poor nutrition: undernutrition or overnutrition. A big belly is now a symptom shared by malnourished children, who lack calories and protein, and overweight residents of the developed world, who suffer clogged arteries and heart disease from eating too much.

Independent of race or economic class, declining quality of life in today's world is manifest in symptoms such as increased asthma in the United States caused by environmental contaminants and the high disease rates in the former Soviet Bloc after decades of unregulated pollution. Even with explicit legal requirements that industries release information on their toxic emissions, many people throughout the world still lack both

information and the decision-making power that would give them any control over the quality of their lives.

Aggrieved about the degraded environment and resulting quality of life in his homeland, Ogoni activist Ken Saro-Wiwa issued a statement shortly before he was executed by the Nigerian government in 1995 saying, "The environment is man's first right. Without a safe environment, man cannot exist to claim other rights, be they political, social, or economic." Kenyan Maathai (2009, p. 249), 2004 winner of the Nobel Peace Prize, has also written, "[I]f we destroy it, we will undermine our own ways of life and ultimately kill ourselves. This is why the environment needs to be at the center of domestic and international policy and practice. If it is not, we don't stand a chance of alleviating poverty in any significant way."

Having ignored this kind of advice for decades, nations are seeing a new kind of refugee attempting to escape environmental degradation and desperate living conditions; the number of international environmental refugees exceeded the number of political refugees around the world for the first time in 1999. Environmental refugees flee homelands devastated by flooding from dam building, extraction of mineral resources, desertification, and unjust policies of national and international institutions. Such degradation preempts many fundamental human rights, including the rights to health, livelihood, culture, privacy, and property.

People have long recognized that human activities that degrade environmental conditions threaten not only the biosphere but also humans' own quality of life. As early as 4500 years ago in Mesopotamia and South Asia, writings revealed an awareness of biodiversity, of natural order among living things, and of consequences of disrupting the biosphere. Throughout history, even as civilization grew increasingly divorced from its natural underpinnings, writers, thinkers, activists, and people from all walks of life have continued to see and extol the benefits of nature to humans' quality of life.

Contemporary society still has the chance to relearn how important the environment is to quality of life. It is encouraging that the United Steelworkers of America in 1990 released a report recognizing that protecting steelworker jobs could not be done by ignoring environmental problems and that the destruction of the environment may pose the greatest threat to their children's future. It is also encouraging that the 2007 Nobel Peace Prize was awarded to a political figure and a group of scientists for their work on climate change.

Environmental Injustice

Making a living from nature's wealth has consistently opened gaps between haves and have-nots, between those who bear the brunt of environmental damage to their home places and those who do not, and between the rights of people alive now and those of future generations; these disparities too are part of biotic impoverishment. Inequitable access to "man's first right" – a healthy local environment – has come to be known as environmental injustice.

Environmental injustices, such as institutional racism, occur in industrial and nonindustrial nations. Injustice can be overt, as when land-use planning sites landfills, incinerators, and hazardous waste facilities in minority communities, or when environmental agencies levy fines for hazardous waste

violations that are lower in minority communities than in white communities.

Less overt, but no less unjust, is the harm done to one community when unsound environmental practices benefit another, as when clear-cut logging in the highlands of north-western North America benefits logging communities while damaging the livelihoods of lowland fishing communities subjected to debris flows, sedimentation, and downstream flooding.

The plight of the working poor and the disparities between rich and poor are also examples of biotic impoverishment within the human community. According to the United Nations Research Institute for Social Development, the collective wealth of the world's 358 billionaires equaled the combined income of the poorest 2.4 billion people in 1994. *Forbes Magazine* put the number of billionaires in early 2010 at 1011, with a total worth of \$3.6 trillion.

In the United States during the last decade of the 20th century, the incomes of poor and middle-class families stagnated or fell, despite a booming stock market. The Center on Budget and Policy Priorities and the Economic Policy Institute reported that between 1988 and 1998, earnings of the poorest fifth of American families rose less than 1%, while earnings of the richest fifth jumped 15%. By the middle of the first decade of the 21st century, Americans' income inequality had become the widest among industrialized nations, with the wealthiest 20% of the population holding 85% of the wealth. The wealthiest Americans continued to prosper even during the global recession late in that decade, while the less well-off kept losing ground.

But perhaps the grossest example of human and environmental domination leading to continued injustice is the creation of a so-called third world to supply raw materials and labor to the dominant European civilization after 1500 and the resulting schism between today's developed and developing nations. Developing regions throughout the world held tremendous stores of natural wealth, some of it – like petroleum – having obvious monetary value in the dominant economies and some having a value invisible to those economies – like vast intact ecosystems. A 2010 United Nations study (TEEB) estimated that even today, Earth's ecosystems account for roughly half to 90% of the source of livelihoods for rural and forest-dwelling peoples; the study calls this value the gross domestic product (GDP) of the poor.

Dominant European civilizations unabashedly exploited this natural wealth and colonized or enslaved the people in whose homelands the wealth was found. But the dominant civilizations also exported their ways of thinking and their economic models to the developing world, not only colonizing places but also effecting what Wangari Maathai has called a colonization of the mind. Although dominant 21st century society tends to dismiss ancient wisdom as irrelevant in the modern world, perhaps the cruelest impoverishment of all is the cultural and spiritual deracination experienced by exploited peoples worldwide.

Exploitation of poor nations and their citizens by richer, consumer countries – and in many cases by the same governments that fought for independence from the colonists while adopting the colonists' attitudes and economic models – persists today in agriculture, wild materials

harvesting, and textile and other manufacturing sweatshops. In the mid-1990s, industrial countries consumed 86% of the globe's aluminum, 81% of its paper, 80% of its iron and steel, 75% of its energy, and 61% of its meat; they are thus responsible for most of the environmental degradation associated with producing these goods. Most of the actual degradation, however, still takes place in developing nations.

As a result, continuing environmental and social injustice – environmental and social impoverishment perpetrated by outsiders and insiders alike – pervades developing nations. Such impoverishment can take the form of wrenching physical dislocation like the massive displacements enforced by China's Three Gorges Dam. It can appear as environmental devastation of homelands and murder of the people who fought to keep their lands, as in the Nigerian government-backed exploitation of Ogoniland's oil reserves by the Shell Petroleum Development Corporation. After Saro-Wiwa's execution, the Ogoni were left, without a voice, to deal with a scarred and oil-polluted landscape.

Despite great advances in the welfare of women and children over the past century, poverty still plagues both groups. Children from impoverished communities, even in affluent nations, suffer from the lethargy and impaired physical and intellectual development known as failure to thrive. Poverty forces many children to work the land or in industrial sweatshops; lack of education prevents them from attaining their intellectual potential. This impoverishment in the lives of women and children is as much a symptom of biotic impoverishment as are deforestation, invasive alien organisms, or species extinctions.

Little by little, community-based conservation and development initiatives are being mounted by local citizens to combat this impoverishment: Witness Maathai's Green Belt Movement, which began with tree planting to restore community landscapes and provide livelihoods for residents, and the rise of ecotourism and microlending (small loans made to individuals, especially women, to start independent businesses) as ways to bring monetary benefits directly to local people without further damaging their environments. Ultimately, one could see all efforts to protect the ethnosphere and the biosphere as a fight for the rights of future generations to an environment that can support them.

Political Instability

Only during the last two decades of the 20th century did environmental issues find a place on international diplomatic agendas, as scholars began calling attention to – and governments began to see – irreversible connections between environmental degradation and national security. British scholar Myers (1993), noting that environmental problems were likely to become predominant causes of conflict in the decades ahead, was one of the first to define a new concept of environmental security. National security threatened by unprecedented environmental changes irrespective of political boundaries will require unprecedented responses altogether different from military actions, he warned. Nations cannot deploy their armies to hold back advancing deserts, rising seas, or the greenhouse effect.

Canadian scholar Homer-Dixon (1999) showed that environmental scarcities – whether created by ecological constraints or sociopolitical factors including growing populations, depletion of renewable resources such as fish or timber, and environmental injustice perpetrated by one segment of a population on another – were fast becoming a permanent, independent cause of civil strife and ethnic violence. He found that such scarcity was helping to drive societies into a self-reinforcing spiral of dysfunction and violence, including terrorism. Environmental and economic injustices worldwide leave no country immune to this type of threat.

Typically, diplomacy has stalled in conflicts over natural resources: arguments over water rights have more than once held up Israeli-Palestinian peace agreements; fights over fish erupted between Canada and the United States, Spain, and Portugal. In contrast, in adopting the Montreal Protocol on Substances That Deplete the Ozone Layer in 1987, governments, nongovernmental organizations, and industry successfully worked together to safeguard part of the environmental commons. The treaty requires signatory nations to curb their use of CFCs and other ozone-destroying chemicals and has been, according to former United Nations secretary general Kofi Annan, perhaps the most successful international agreement to date.

Cumulative Effects

If scientists have learned anything about the factors leading to biotic impoverishment, they have learned that the factors' cumulative effects can take on surprising dimensions. As scholars like Fagan (1999) and Diamond (2005) have chronicled, the multiple stresses of global climatic cycles such as El Niño, natural events like droughts or floods, resource depletion, and social upheaval have shaped the fates of civilizations.

Societies as far-flung as ancient Egypt, Peru, the American Southwest, and Easter Island prospered and collapsed because of unwise management of their environments. The city of Ubar, built on desert sands in what is now southern Oman, literally disappeared into the sinkhole created by drawing too much water out of its great well. In modern Sahelian Africa, a combination of well digging and improved medical care and sanitation led to a threefold population increase; sedentary ways, heavy taxes imposed by a colonial government, and an impoverished people took the place of a nomadic culture evolved within the desert's realities.

During the first decade of the 21st century, numerous natural disasters befell nations around the world: wildfires in Australia, Bolivia, Canada, and Russia; flooding in China, India, Romania, and West Africa; devastating hurricanes and typhoons in the Caribbean, Philippines, Taiwan, and southeastern United States; catastrophic landslides and floods in China, Guatemala, Pakistan, and Portugal; and destructive earthquakes in Chile, China, Haiti, Indonesia, and Pakistan. Neither the rains nor the earthquakes were caused by human activity, but the cumulative effects of human land uses and management practices – from dikes separating the Mississippi from its floodplain to deforestation in Haiti – made the losses of human life and property much worse than they might have been otherwise.

Root Causes of Human Impact

The ultimate cause of humans' massive environmental impact is our individual and collective consumptive and reproductive behavior, which has given us spectacular success as a species. But the very things that enabled humans to thrive in nearly every environment have magnified our impacts on those environments, and the technological and political steps we take to mitigate our impacts often aggravate them. Too many of us simply take too much from the natural world and ask it to absorb too much waste.

Fragmented Worldviews, Fragmented Worlds

For most of human history, people remained tied to their natural surroundings. Even as agriculture, writing, and technology advanced, barriers of geography, language, and culture kept humans a diverse lot, each group depending on mostly local and regional knowledge about where and when to find resources necessary for survival. Their worldviews, and resulting economies, reflected this dependency.

For example, in northwestern North America starting about 3000 years ago, a native economy centered on the abundance of salmon. At its core was the concept of the gift and a belief system that treated all parts of the Earth – animate and inanimate – as equal members of a community. In this and other ancient gift economies, a gift was not a possession that could be owned; rather, it had to be passed on, creating a cycle of obligatory returns. Individuals or tribes gained prestige through the size of their gifts, not the amount of wealth they accumulated.

This system coevolved with the migratory habits of the salmon, which moved en masse upriver to spawn each year. Because the Indians viewed salmon as equals to themselves, killing salmon represented a gift of food from salmon to people. Fishers were obligated to treat salmon with respect or risk losing this vital gift. The exchange of gifts between salmon and humans – food for respectful treatment – minimized waste and overharvest and ensured a continuous supply of food. Further, the perennial trading of gifts among the people effectively redistributed the natural wealth brought each year by fluctuating populations of migrating fish, leveling out the boom-and-bust cycles that usually accompany reliance on an uncertain resource.

In modern times, the gift economy along with the egalitarian worldview that accompanied it, has been eclipsed by a redistributive economy tied not to an exchange of gifts with nature but to the exploitation of nature and to the technologies that enhance that exploitation. Nature became a resource for humans, rather than an equal to humans. In economic terms, natural resources fell under the heading of 'land' in an economic trinity comprising three factors of production: land, labor, and capital. Land and resources, including crops, became commodities – expendable or easily substitutable forms of capital – whose value was determined solely by their value in the human marketplace.

In 1776 Adam Smith published his famous *Inquiry into the Nature and Causes of the Wealth of Nations*, in which he argued that society is merely the sum of its individuals, that the social good is the sum of individual wants, and that the

market (the so-called invisible hand) automatically guides individual behavior to the common good. Crucial to his theories were division of labor and the idea that all the factors of production were freely mobile. His mechanistic views created an economic rationale for no longer regarding individuals as members of a community linked by ethical, social, and ecological bonds.

About the same time, fueling and fueled by the beginnings of the Industrial Revolution, the study of the natural world was morphing into modern physics, chemistry, geology, and biology. Before the mid-19 century, those who studied the natural world – early 19 century German biogeographer Baron Alexander von Humboldt and his disciple Charles Darwin among them – took an integrated view of science and nature, including humans. Both scientists regarded the understanding of the complex interdependencies among living things as the noblest and most important result of scientific inquiry.

But this integrated natural philosophy was soon supplanted by more atomistic views, which fit better with industrialization. Mass production of new machines relied on division of labor and interchangeable parts. Like automobiles on an assembly line, natural phenomena too were broken down into their supposed component parts in a reductionism that has dominated science ever since. Rushing to gain in-depth, specialized knowledge, science and society lost sight of the need to tie the knowledge together. Disciplinary specialization replaced integrative scholarship.

Neoclassical economics, which arose around 1870, ushered in the economic worldview that rules today. A good's value was no longer tied to the labor required to make it but derived instead from its scarcity. A good's price was determined only by the interaction of supply and demand. As part of 'land,' natural resources therefore became part of the human economy, rather than the material foundation making the human economy possible. Because of its doctrine of infinite substitutability, neoclassical economics rejects any limits on growth; forgotten are the classical economic thinkers and contemporaries of von Humboldt, including Thomas Malthus and John Stuart Mill, who saw limits to the growth of human population and material well-being.

Consequently, the 19th and 20th centuries saw the rise to dominance of economic indicators that fostered the economic invisibility of nature, misleading society about the relevance of Earth's living systems to human well-being. Among the worst offenders in this regard are gross national product (GNP) and its cousin, GDP. GNP measures the value of goods and services produced by a nation's citizens or companies, regardless of their location around the globe. GDP, in contrast, measures the value of goods and services produced within a country's borders, regardless of who generates those goods and services.

In effect, both GNP and GDP measure money changing hands, no matter what the money pays for; they make no distinction between what is desirable and undesirable, between costs and benefits. Both indicators ignore important aspects of the economy like unpaid work or nonmonetary contributions to human fulfillment – parenting, volunteering, checking books out of the library. Worse, the indicators also omit social and environmental costs, such as pollution, illness, or resource depletion; they only add and do not subtract. GDP math adds in the value of paid daycare or a stay in the hospital

and ignores the value of unpaid parenting or being cared for at home by friends. It adds in the value of timber sold, but fails to subtract the losses in biodiversity, watershed protection, or climate regulation that come when a forest is cut.

Efforts have been made in the past few decades to create less blinkered economic indicators. Social scientists Herman Daly and John Cobb in 1989 developed an index of sustainable economic welfare, which adjusts the United States' GNP by adding in environmental good things and subtracting environmental bad things. Public expenditures on education, for example, are weighted as "goods" while costs of pollution cleanup, depletion of natural resources, and treating environment-related illnesses are counted as 'bads.' Unlike the soaring GDP of recent decades, this index of sustainable economic welfare remained nearly unchanged over the same period.

Still other work aims to reveal nature's worth in monetary terms by assigning dollar values to ecological goods and services. A 1997 study by ecologist David Pimentel and colleagues calculated separate values for specific biological services, such as soil formation, crop breeding, or pollination; by summing these figures, these researchers estimated the total economic benefits of biodiversity for the United States at \$319 billion – 5% of US GDP at the time – and for the world at \$2928 billion. A 2000 analysis by Pimentel and colleagues reported that the approximately 50,000 nonnative species in the United States cause major environmental damage and reparation costs amounting to \$137 billion a year.

As part of the United Nations International Year of Biodiversity in 2010, several studies have translated the value of the world's ecosystems into dollar values. One report estimated the worth of crucial ecosystem services delivered to humans by living systems at \$21–72 trillion per year – comparable to a world gross national income of \$58 trillion in 2008. Another study reported, among other things, that as many as 500 million people worldwide depend on coral reefs – valued between \$30 billion and \$172 billion a year – for fisheries, tourism, and protection from ocean storms and high waves, services threatened by warmer and more acidic seas.

Although a monetary approach does not create a comprehensive indicator of environmental condition, it certainly points out that ecological values ignored by the global economy are enormous.

Too Many Consuming Too Much

The US Census Bureau predicts that by 2012, the global human population will top 7 billion – having grown by nearly 1 billion people during the decade between the first and second editions of this encyclopedia. From the appearance of *H. sapiens* about 200,000 years ago, it took humans until 1804 to reach their first billion, 123 years to double to 2 billion, and 33 years to achieve 3 billion. Human population doubled again from 3 to 6 billion in about 40 years – before most post-World War II baby boomers reached retirement age. Even with fertility rates declining in developed countries, China, and some developing countries where women are gaining education and economic power, and with pandemics like AIDS claiming more lives, the Census Bureau predicts that world population will reach 9 billion by 2044.

Figure 1 Relationships among the natural, social, and economic systems on Earth. Human economies may be thought of as icing atop a two-layer cake. The economic icing is eroding the human social and natural layers beneath it, threatening the foundation and sustainability of all three systems. Modified from Karr JR and Chu EW (1995) Ecological integrity: Reclaiming lost connections. In: Westra L and Lemons J (eds.) *Perspectives in Ecological Integrity*, pp 34–48. Dordrecht, Netherlands: Kluwer Academic.

Humans appropriate about 40% of global plant production, 54% of Earth's freshwater runoff, and enough of the ocean's bounty to have depleted 63% of assessed marine fish stocks. In energy terms, one person's food consumption amounts to 2500–3000 calories a day, about the same as that of a common dolphin. But with all the other energy and materials humans use, global per capita energy and material consumption have soared even faster than population growth over the past 50 years. Now, instead of coevolving with a natural economy, global society is consuming the foundations of that economy, impoverishing Earth's living systems, and undermining the foundations of its own existence (Figure 1).

Measuring Environmental Impacts

For most of the 20th century, environmental measurements, or indicators, tracked primarily two classes of information: counts of activities directed at environmental protection and the supply of products to people. Regulatory agencies are typically preoccupied with legislation, permitting, or enforcement, such as the numbers of environmental laws passed, permits issued, enforcement actions taken, or treatment plants constructed. Resource protection agencies concentrate on resource harvest and allocation. Water managers, for example, measure water quantity; they allocate water to domestic, industrial, and agricultural uses but seldom make it a priority to reserve supplies for sustaining aquatic life, to protect scenic and recreational values, or simply to maintain the water cycle. Foresters, farmers, and fishers count board-feet of timber, bushels of grain, and tons of fish harvested. Governmental and nongovernmental organizations charged with protecting biological resources also keep counts of threatened and endangered species.

As in the parable of the three blind men and the elephant – each of whom thinks the elephant looks like the one body part he can touch – these or similar indicators measure only

one aspect of environmental quality. Counting bureaucratic achievements focuses on actions rather than on information about real ecological status and trends. Measurements of resource supply keep track of commodity production, not necessarily a system's capacity to continue supplying that commodity. And measuring only what we remove from natural systems, as if we were taking out the interest on a savings account, overlooks the fact that we are usually depleting principal as well.

Even biologists' counts of threatened and endangered species – which would seem to measure biotic impoverishment directly – still focus narrowly on biological parts, not ecological wholes. Enumerating threatened and endangered species is just like counting any other commodity. It brings our attention to a system already in trouble, perhaps too late. And it subtly reinforces our view that we know which parts of the biota are most important.

Society needs to rethink its use of available environmental indicators, and it needs to develop new indicators that represent current conditions and trends in the systems humans depend on (Table 2). It particularly needs objective measures more directly tied to the condition, or health, of the environment so that people can judge whether their actions are compromising that condition.

Such measures should be quantitative, yet easy to understand and communicate; they should be cost-effective and applicable in many circumstances. Unlike narrow criteria tracking only administrative, commodity, or endangered species numbers, they should provide reliable signals about status and trends in ecological systems. Ideally, effective indicators should describe the present condition of a place, aid in diagnosing the underlying causes of that condition, and make predictions about future trends. They should reveal not only risks from present activities but also potential benefits from alternative management decisions.

Most important, these indicators should, either singly or in combination, give information explicitly about living systems. Measurements of physical or chemical factors can sometimes act as surrogates for direct biological measurements, but only when the connection between those measures and living systems is clearly understood. Too often we make assumptions – when water managers assume that chemically clean water equals a healthy aquatic biota, for example – that turn out to be wrong and fail to protect living systems.

General Sustainability Indexes

As environmental concerns have become more urgent – and governmental and nongovernmental organizations have struggled to define and implement the concept of sustainable development – the effort has grown to create indicator systems that explicitly direct the public's and policymakers' attention to the value of living things. Moving well past solely economic indexes like GDP, several indexes now integrate ecological, social, and economic well-being.

The index of environmental trends for nine industrialized countries, developed by the nonprofit National Center for Economic and Security Alternatives, incorporates ratings of air, land, and water quality; chemical and waste generation; and

Table 2 Plausible indicators of environmental quality^a*Indirect depletion of living systems through alterations in physical and chemical environments*

1. Degradation of water (chemical contaminant concentrations, river flows, rainfall, runoff)
2. Soil depletion (erosion rates, desertification rates, salt accumulation in soils)
3. Chemical contamination (pollutant and toxic emissions, pollutant and toxic concentrations in air, water, soil, and living organisms)
4. Altered biogeochemical cycles (river flows and lake levels; amount of nutrients going into water bodies, or nutrient loading; nutrient concentrations in water bodies; chlorophyll concentrations, reflecting nutrient-triggered algal blooms; oxygen depletion in water bodies; trophic status of lakes; changes in air and soil chemistry; atmospheric greenhouse gas concentrations)
5. Global climate change (atmospheric greenhouse gas concentrations, change in atmospheric temperatures, distribution and intensity of severe storms or droughts)

Direct depletion of nonhuman life

1. Overharvest of renewable resources such as fish and timber (tons of fish harvested; for a given anadromous fish population, number of adult fish returning to rivers to spawn; hatchery fish released and recovered; board-feet of timber harvested; forest regrowth rates; quantity of standing timber; ecological footprints)
2. Habitat fragmentation and destruction (area of remaining grassland, wetland, and other habitats; landscape connectivity; rates of habitat destruction)
3. Biotic homogenization (number of extinct, threatened, and endangered taxonomic groups; spread of nonindigenous species; local or regional diversity; damage and reparation costs due to invasions or extinctions; major relocations in species distributions)
4. Genetic engineering (diversity among cultivated crop strains, genetic diversity within strains, escape of genetically engineered organisms or traits to wild populations)

Direct degradation of human life

1. Emerging and reemerging diseases (death or infection rates caused by diseases, geographic spread of diseases, recovery rates, frequency and spread of resistance to antibiotics and other drugs)
2. Loss of cultural diversity (extinction of cultures, death of languages)
3. Reduced quality of life (population size and growth; starvation, malnutrition, and obesity rates; infant mortality rates; teen pregnancy rates; literacy rates; rates of stress and other diseases of affluence; length of work week; child or other forced labor; changes in death rates or average life spans)
4. Environmental injustice (siting of toxic waste dumps or waste emissions relative to resident communities, economic exploitation of certain groups, worker strikes, wage and income gaps, unemployment rates for different economic sectors)
5. Political instability (frequency of domestic and international strife, environmental terrorism rates, number of environmental refugees, genocide)
6. Cumulative effects (frequency of catastrophic natural disasters; costs of weather-related property damage; human death tolls; government subsidies of environmentally destructive activities such as fishery overcapitalization, below-cost timber sales, water projects, and agricultural supports; replacement costs for ecological services; pricing that reflects environmental costs; "green" taxes; rise in polycultural agricultural practices; number of organic farms)

^aThese indicators have been or could be used to monitor status and trends in environmental quality, including dimensions of biotic impoverishment. Without a full spectrum of indicators, however, and without coupling them to direct measures of biological condition, only a partial view of the degree of biotic impoverishment will emerge.

energy use since 1970. By its 1995 rankings, environmental quality in the United States had gone down by 22% since 1970, while Denmark had declined by 11%.

In 2000, world leaders, supported by the United Nations Development Programme, defined a set of eight millennium development goals to be attained by 2015, which combine poverty, education, employment, and environmental sustainability. They include human rights and health goals – such as universal primary education, gender equality, and combating AIDS and other diseases – as well as ensuring environmental sustainability. In the decade since the program began, progress has been made in reducing poverty; expanding educational opportunities for children, especially in Africa; slowing deforestation; and providing better water for many people, among others. But progress controlling climate change, halting biodiversity loss, and achieving gender equality has lagged.

A later environmental performance index spearheaded by Yale and Columbia universities ranks 163 countries on 25 performance indicators in 10 well-established policy categories to determine whether and how well countries are meeting established environmental goals. This index incorporates measurements addressing environmental stresses to human health plus ecosystem health and natural resource management, collectively referred to as ecosystem vitality. The categories representing environmental health include the environmental burden of disease and the effects of air and water quality on human health. Those representing ecosystem vitality include air and water resources for ecosystems; biodiversity and habitat; and climate change, among others.

Although hampered by data gaps and the inability to track changes in countries' performance through time, the index provides a sense of countries' relative performance with regard to the environmental challenges faced by all. Top performers in the 2010 rankings included Iceland, Switzerland, Costa Rica, and Sweden. The United States ranked 61st well below Japan and nations in the European Union.

Ecological Footprints

A resource-accounting approach pioneered in the 1990s by geographers Rees and Wackernagel (1996) translates humans' impact on nature, particularly resource consumption, into a metaphorical ecological footprint. This accounting estimates the area required by a city, town, nation, or other human community to produce consumed resources and absorb generated wastes; it then compares the physical area occupied by a city or country with the area required to supply that city or country's needs. The 29 largest cities of Baltic Europe, for example, appropriate areas of forest, agricultural, marine, and wetland ecosystems that are at least 565–1130 times larger than the areas of the cities themselves.

According to the Global Footprint Network, national ecological footprints in 2010 ranged from a high of 10.7 hectares per person for the United Arab Emirates to 0.4 hectares per person for Timor-Leste and 0.6 for Afghanistan and Bangladesh. The United States' ecological footprint – 8.0 hectares per person – tied for fourth among 152 nations with populations of at least 1 million. One-hundred and four of these nations operate under ecological deficits; that is, their

consumption exceeds the biological capacity of their lands and waters to provide needed resources and absorb their wastes. At their present rates of consumption, these nations are therefore overexploiting either their own resources or those of other nations.

By ecological footprint accounting, raising the nearly 7 billion people on Earth in the early 21st century to living standards – and thus ecological footprints – equal to those in the United States would require four planets more than the only one we have. Clearly, humans are consuming more resources, and discarding more waste, than Earth's living systems can produce or absorb in a given time period. This gap is the global sustainability gap the world now faces.

Measuring the State of Living Systems

Most environmental indexes and accounting systems are still human centered; they still do not measure the condition of the biosphere itself. We may know that biodiversity's services are worth huge sums of money and that our hometown's ecological footprint is much bigger than the town's physical footprint, but how do we know whether specific actions damage living systems or that other actions benefit them? How do we know if aggregate human activity is diminishing life on Earth? To answer this question, we need measures that directly assess the condition of living systems.

Biological assessment directly measures the attributes of living systems to determine the condition of a specific landscape. The very presence of thriving living systems – sea otters and kelp forests off the central California coast; salmon, orcas, and herring in Pacific Northwest waters; monk seals in the Mediterranean Sea – says that the conditions those organisms need to survive are also present. A biota is thus the most direct and integrative indicator of local, regional, or global biological condition. Biological assessments give us a way to evaluate whether monetary valuations, sustainability indexes, and ecological footprints are telling the truth about human impact on the biosphere. Biological assessments permit a new level of integration because living systems, including human cultures, register the accumulated effects of all forms of degradation caused by human actions.

Direct, comprehensive biological monitoring and assessment has been done for many aquatic systems; measures are less developed for terrestrial systems. The index of biological integrity (IBI), for example, was developed in 1981 to assess the health of streams in the US Midwest and has since helped scientists, resource managers, and citizen volunteers understand, protect, and restore rivers in at least 67 countries worldwide (Karr 2006). Borrowing from the same page as more recent sustainability indexes, IBI takes the concept behind economic indexes like GDP or the consumer price index – that of multiple indicators integrated into a multi-metric index – and applies it to animals and plants in bodies of water or other environments. The specific measurements (Table 3) are sensitive to a broad range of human effects in waterways, such as sedimentation, nutrient enrichment, toxic chemicals, physical habitat destruction, and altered flows. The resulting index combines the responses of biological parts such as species, as well as processes such as food web dynamics, to human actions.

Table 3 Biological attributes in two indexes of biological integrity

<i>Benthic invertebrates</i>	<i>Fish</i>
Total number of taxa	Number of native fish species
Number of mayfly taxa	Number of riffle-benthic insectivore species
Number of stonefly taxa	Number of water-column insectivore species
Number of caddisfly taxa	Number of pool-benthic insectivore species
Number of intolerant taxa	Number of intolerant species
Number of long-lived taxa	Relative abundance of omnivores
Number of clinger taxa	Relative abundance of insectivores
Relative abundance of tolerant taxa	Relative abundance of tolerant taxa
Relative abundance of predators	Relative abundance of top carnivores
Dominance	Relative abundance of diseased or deformed individuals

Indexes of biological integrity have been developed for a number of aquatic and terrestrial environments; the most widely used indexes for assessing rivers examine fishes and benthic (bottom-dwelling) invertebrates. These groups are abundant and easily sampled, and the species living in virtually any water body represent a diversity of anatomical, ecological, and behavioral adaptations. As humans alter watersheds and water bodies, changes occur in taxonomic richness (biodiversity), species composition (which species are present), individual health, and feeding and reproductive relationships.

Sampling the inhabitants of a stream can tell us much about that stream and its landscape. Biological diversity is higher upstream of wastewater treatment plants than downstream, for example, whereas, at the same location, year-to-year variation is low (Figure 2). Biological sampling can also reveal differences between urban and rural streams. For instance, samples of invertebrates from one of the best streams in rural King County, in the US state of Washington, contain 27 kinds, or taxa, of invertebrates; similar samples from an urban stream in the city of Seattle contain only 7. The rural stream has 18 taxa of mayflies, stoneflies, and caddisflies; the urban stream, only 2 or 3. When these and other metrics are combined in an index based on invertebrates, the resulting benthic IBI (B-IBI) ranks the condition, or health, of a stream numerically (Table 4).

A benthic IBI can also be used to compare sites in different regions. Areas in Wyoming's Grand Teton National Park where human visitors are rare have near-maximum B-IBIs. Streams with moderate recreation taking place in their watersheds have B-IBIs that are not significantly lower than those with no human presence, but places where recreation is heavy are clearly damaged. Urban streams in the nearby town of Jackson are even more degraded, yet not as bad as urban streams in Seattle.

Nation-specific biological assessments also can be and are being done. The US Environmental Protection Agency (2006), for example, performed a nationwide survey of stream condition using an IBI-like multimetric index. The survey found that 28% of US stream miles were in good condition in

Figure 2 (a) Biodiversity is higher at sites upstream of wastewater treatment outfalls than downstream. At Tickle Creek near Portland, Oregon (United States), taxa richness differed little between years but differed dramatically between sites upstream of a wastewater outfall and sites downstream. (b) Taxa richness also differed between two creeks with wastewater outfalls (Tickle and North Fork Deep) and one creek without an outfall (Foster). All three streams flowed through watersheds with similar land uses.

comparison with least-disturbed reference sites in their regions, 25% were in fair condition, and 42% were in poor condition (5% were not assessed). The agency has been expanding this effort to include other water resource types, including coastal waters, coral reefs, lakes, large rivers, and wetlands.

Since 2000, the [Heinz Center \(2008\)](#) has published two editions of its report on the state of US ecosystems, which seek to capture a view of the large-scale patterns, conditions, and trends across the United States. The center defined and compiled a select set of indicators – specific variables tracking ecosystem extent and pattern, chemical and physical characteristics, biological components, and goods and services derived from the natural world – for six key ecosystems: coasts and oceans, farmlands, forests, fresh waters, grasslands and shrublands, and urban and suburban landscapes.

Among the many conclusions of the 2008 report were that the acreage burned every year by wildfires was on the increase; nonnative fish had invaded nearly every watershed in the lower 48 states; and chemical contaminants were found in virtually all streams and most groundwater wells, often at levels above those set to protect human health or wildlife. On the plus side, ecosystems were increasing their storage of carbon, soil quality was improving, and crop yields had grown significantly.

The massive international UN [Millennium Ecosystem Assessment \(2005\)](#) remains the gold standard for synthesizing ecological conditions at a variety of scales. From 2001 through 2005, the project examined the full range of global ecosystems – from those relatively undisturbed, such as natural forests, to landscapes with mixed patterns of human use to ecosystems intensively managed and modified by humans, such as agricultural land and urban areas – and communicated its findings in terms of the consequences of ecosystem change for human well-being.

The resulting set of reports drew attention to the many kinds of services people derive from ecosystems, specifically, supporting services, such as photosynthesis, soil formation, and waste absorption; regulating services, such as climate and flood control and maintenance of water quality; provisioning services, such as food, wood, and nature's pharmacopoeia;

Table 4 Biological responses to different land uses

Region	Land use	B-IBI ^a
King County, Washington, USA	Rural	46
	Urban Seattle	12
Grand Teton Region, Wyoming, USA	Little or no human activity	48
	Light to moderate recreation	44
	Heavy recreation	32
	Urban Jackson Hole	21
	Upstream of wastewater treatment plant	
Clackamas County, Oregon, USA ^b	Tickle Creek up (1997, 1998)	40, 42
	Foster Creek	34
	Downstream of wastewater treatment plant	
	Tickle Creek down (1997, 1998)	14, 16
	North Fork Deep Creek	10

^aBenthic index of biological integrity: the highest possible score is 50, the lowest is 10.

^bSee [Fig. 2](#) for graphs of selected B-IBI metrics at these sites.

and cultural services from scientific to spiritual. In addition, the reports explicitly tied the status of diverse ecosystems and their capacity to provide these services to human needs as varied as food and health, personal safety and security, and social cohesion. Even while recognizing that the human species is buffered against ecological changes by culture and technology, the reports highlighted our fundamental dependence on the flow of ecosystem services and our direct responsibility for the many faces of biotic impoverishment.

Among other findings, the assessment found that 60% of the services provided by ecosystems are being degraded at levels that derail efforts to stem poverty, hunger, and disease among the poor everywhere. Government subsidies that provide incentives to overharvest natural resources are a leading cause of the decline in renewable natural resources. Such declines are not limited to coral reefs and tropical forests, which have been on the public's radar for some time; they are pervasive in grasslands, deserts, mountains, and other landscapes as well. Moreover, the degradation of ecosystem services could grow worse during the first half of the 21st century, effectively blocking achievement of the United Nations' eight millennium development goals.

The core message embodied in ecological, especially biological, assessments is that preventing harmful environmental impacts goes beyond narrow protection of clean water or clear skies, even beyond protecting single desired species. Certain species may be valuable for commerce or sport, but these species do not exist in isolation. We cannot predict which organisms are vital for the survival of commercial species or species we want for other reasons. Failing to protect all organisms – from microbes and fungi to plants, invertebrates, and vertebrates – ignores the key contributions of these groups to healthy biotic communities. No matter how important a particular species is to humans, it cannot persist outside the biological context that sustains it. Direct biological assessment objectively measures this context and is fundamental to advancing the kinds of syntheses like those of the Millennium Ecosystem Assessment.

Recognizing and Managing Environmental Impacts

Every animal is alert to dangers in its environment. A microscopic protozoan gliding through water responds to light, temperature, and chemicals in its path, turning away at the first sign of something noxious. A bird looking for food must decide when to pursue prey and when not, because pursuit might expose the bird to predators. The bird might risk pursuit when it is hungry but not when it has young to protect. Animals that assess risks properly and adjust their behavior are more likely to survive; in nature, flawed risk assessment often means death or the end of a genetic line.

Humans, too, are natural risk assessors. Each person chooses whether to smoke or drink, fly or take the train, drive a car or ride a motorcycle and at what speeds. Each decision is the result of a partially objective, partially subjective internal calculus that weighs benefits and risks against one another.

Risk is a combination of two factors: the numerical probability that an adverse event will occur and the consequences of the adverse event. People may not always have the right

signals about these two factors, however, and may base their risk calculus on the wrong clues. City dwellers in the United States generally feel that it is safer to drive home on a Saturday night than to fly in an airplane, for example. Even though the numerical odds of an accident are much higher on the highway than in the air, people fear more the consequences of an airplane falling out of the sky.

Human society also strives to reduce its collective exposure to risks. Governments seldom hesitate to use military power to defend their sovereignty or, albeit more reluctantly, their regulatory power to reduce workplace risks and risks associated with consumer products like automobiles. But people and their governments have been much less successful in defining and reducing a broad range of ecological risks, largely because they have denied that the threats are real.

Policies and plans generated by economists, technologists, engineers, and even ecologists typically assume that the lost and damaged components of living systems are unimportant or can be repaired or replaced. Widespread ecological degradation has resulted directly from the failure of modern society to properly assess the ecological risks it faces. Like the fate of Old Kingdom Egypt or Easter Island, our civilization's future depends on our ability to recognize this deficiency and correct it.

Risk assessment as formally practiced by various government agencies began as a way to evaluate the effects of toxic substances on human health, usually the effects of single substances, such as pollutants or drugs, from single sources, such as a chemical plant. During the 1990s, the focus widened to encompass mixtures of substances and also ecological risks. Ecological risk assessment by the US Environmental Protection Agency (1998) asks five questions: Is there a problem? What is the nature of the problem? What are the exposure and ecological effects? (A hazard to which no one or nothing is exposed is not considered to pose any risk.) How can we summarize and explain the problem to affected parties, both at-risk populations and those whose activities would be curtailed? How can we manage the risks?

Even though these are good questions, ecological risk management has not made any visible headway in stemming biotic impoverishment. Its central failing comes from an inability to correctly answer the second question, What is the nature of the problem? Our present political, social, and economic systems simply do not give us the right clues about what is at risk. None of society's most familiar indicators – whether GDP or number of threatened and endangered species – measure the consequences, or risks, of losing living systems.

If biotic impoverishment is the problem, then it only makes sense to direct environmental policy toward protecting the integrity of biotic systems. Integrity implies a wholeness or unimpaired condition. In present biological usage, integrity refers to the condition at sites with little or no influence from human activity; the organisms there are the products of natural evolutionary and biogeographic processes in the absence of humans. Tying the concept of integrity to an evolutionary framework provides a benchmark against which to evaluate sites that humans have altered.

Directing policy toward protecting biological integrity – as called for in the United States' Clean Water Act, Canada's

National Park Act, and the European Union's Water Framework Directive, among others – does not, however, mean that humans must cease all activity that interferes with a “pristine” earthly biota. The demands of feeding, clothing, and housing billions of people mean that few places on Earth will maintain a biota with evolutionary and biogeographic integrity. Rather, because humans depend on living systems, it is in our interest to manage our activities so they do not compromise a place's capacity to support those activities in the future; that capacity can be called ecological health.

Ecological health describes the preferred state of sites heavily used for human purposes: cities, croplands, tree farms, water bodies stocked for fish, and the like. At these places, it is impractical to set a goal of integrity in an evolutionary sense, but we should avoid practices that damage these places to the point where we can no longer derive the intended benefits indefinitely. For example, agricultural practices that leave behind saline soils, depress regional water tables, and erode fertile topsoil faster than it can be renewed destroy the land's biological capacity for agriculture; such practices are unhealthy in both ecological and economic terms.

Biological integrity as a policy goal redirects our focus away from maximizing goods and services for the human economy toward ways to manage human affairs within the bounds set by the natural economy. It begins to turn our attention away from questions such as, How much stress can landscapes and ecosystems absorb? to ones such as, How can responsible human actions protect and restore ecosystems? In contrast to risk assessment, striving to protect biological integrity is more likely to lead away from mandated corrective actions in the form of technological fixes for environmental problems and toward practices that prevent ecological degradation and encourage ecological restoration.

Leopold (1949, pp. 224–225), in *A Sand County Almanac*, was the first to invoke the concept of integrity in an ecological sense: “A thing is right when it tends to preserve the integrity, stability, and beauty of the biotic community. It is wrong when it tends otherwise.” Managing for biological integrity requires the kind of ethical commitment inherent in Leopold's words. We are called to curb consumerism and limit population size, to embrace less-selfish attitudes toward land stewardship, and to understand that the biosphere matters. Instead of calling on human technical and spiritual well-springs to manage resources, we have to call on them for managing human affairs.

We have to find and use appropriate measurements for all the factors contributing to biotic impoverishment, be they climate change, overharvesting, agriculture, or environmental injustice. Measurement of environmental impact founded on the evolutionary idea of integrity allow us to directly assess biotic condition and to compare that condition with what might be expected in a place with little or no human influence. At least then we can make an informed choice: continue with activities that degrade biotic condition or think of an alternative.

The ecological world is a complex, variable, and often unpredictable system. When managing for ecological risks, people and their governments need to expect the unexpected and develop formal, yet flexible means of coping with environmental surprises. Rather than plunge ahead with projects

entailing ecological risks because they can be done, decision makers should follow the precautionary principle, which holds that regulators should act to prevent potential environmental harm even in the absence of certainty. It acknowledges the existence of uncertainty rather than deny it, and it includes mechanisms to safeguard against potentially harmful effects.

Although inappropriate ecological risk assessment and management are more often the norm today, modern institutions are capable of recognizing ecological threats correctly and responding to them in time, as they did with the Montreal Protocol. A decade after the agreement's adoption, satellite measurements in the stratosphere indicated that ozone-depleting pollutants were in fact on the decline. Given the treaty's success, some policy experts have suggested using it to help curb global warming. Specifically, negotiators at the 2010 annual meeting of signatory parties were considering a proposed expansion of the ozone treaty to phase out the production and use of industrial chemicals called hydrofluorocarbons, which have thousands of times the global warming potential of carbon dioxide. Even though the Montreal Protocol was not designed to fight climate change, policymakers in favor of the new proposal say that it could and should be used to achieve broader environmental objectives.

Reuniting the Fragments

Early in the 20th century, two sciences of “home maintenance” began to flourish: the young science of ecology (from the Greek *oikos*, meaning home) and a maturing neoclassical economics (also from *oikos*). Ecology arose to document and understand the interactions between organisms and their living and nonliving surroundings – in essence, how organisms make a living in the natural economy. In fact, Ernst Haeckel, who coined the term in the 1860s, defined ecology in an 1870 article as the body of knowledge concerning the economy of nature. Neoclassical economics, in contrast, reinforced humans' self-appointed dominion over nature's wealth. It brought unparalleled gains in societal welfare in some places, but it also divorced the human economy from the natural one on which it stands (see Figure 1).

By now it is clear to economists and ecologists alike that human actions and their effects have reached scales unprecedented in the history of life. We have altered Earth's physical and chemical environment, changed the planet's water and nutrient cycles, and perturbed its climate. We have unleashed the greatest mass extinction in 65 My and distorted the structure and function of nonhuman and human communities worldwide. In trying to make our own living, we have jeopardized the Earth's capacity to sustain other species and our own species as well. We are losing the *bio* in biosphere.

Now, faced with these unprecedented losses, we need to understand – not deny – the ecological consequences of what we do. We urgently need a new science and art of home maintenance, one that sees the human species' role as ecosystem engineer for what it has become and reconnects human and natural economies. This new science can help us understand and correctly interpret the consequences of

human-driven change. By using indicators that measure what matters for sustaining living systems, this new science can make nature visible again and shed new light on the value of the ancient heritage we share with the larger biosphere. It can help us reunite the fragments of our worldview and re-create ethical, social, and ecological bonds that were put aside two centuries ago in the name of progress. And such a science can enable us to reengineer our own social, political, and economic institutions instead of ecosystems. This we must do – now – before we impoverish the biosphere and ourselves for all time.

Glossary

Adaptive management A systematic, cyclical process for continually improving management policies and practices based on lessons learned from operational programs.

Analysis A process of exploring and estimating parameters of data, gathered with statistical procedures, to test previously established hypotheses.

Biodiversity assessment The identification and classification of species, habitats, and communities, within a given area or region. The overall purpose is to provide information needed to evaluate whether management is necessary to conserve biological diversity. Assessments also provide data and information that can be applied for programs of scientific inquiry.

Indicators Species or communities that enable an evaluation of environmental conditions and detect changes. Indicator species are normally surrogates of other species in the area of interest and are usually sensitive to environmental change. Environmental variables may also be used as indicators.

Monitoring The repeated collection and analysis of observations and measurements to evaluate changes in populations of species and environmental conditions. Monitoring also helps in assessing progress toward meeting a management objective. Monitoring can serve as a warning system, alerting managers that changes in biodiversity may require changes in biodiversity management regimes to ensure protection of biological resources.

Sampling Refers to the process of data collection. A protocol must be developed to direct sampling that includes sampling objectives, parameter to be measured, sample unit determination, permanent or temporary sampling, number of samples, and method of sample selection.

Uncertainty Describes the condition whereby managers have a lack of data, or unreliable, error-prone data of biodiversity that prevents them from defining the best course of management action. Uncertainty can be overcome through a well-designed adaptive management program.

Why are we interested in assessing and monitoring biodiversity? Accurate information on the status of components and processes of ecosystems is essential for the long-term maintenance of biodiversity, and its sustainable use. The selection of biotic indicators observable or linked across different spatial and temporal scales, are important to detect trends that can result in management practices (Feld *et al.*, 2009). Biodiversity assessment across spatial and temporal scales, at different levels of biological organization, and in terms of various attributes, processes, and functions of biodiversity, is critical to our understanding of ecosystem functioning and formulation of management objectives (Ash, 2009). In addition, most ecosystems are under severe pressure, either from increasing primary and secondary human impacts, or from climatic changes (Dallmeier *et al.*, 2010).

Biodiversity monitoring and assessment programs (BMAP) provide a process which collects and reports scientific information to be used for natural resource management. The first task in developing the BMAP program is to define the objectives. Then, a baseline biological assessment is often necessary to determine what kinds of species and habitats need to be considered as part of the program. After the assessment has been completed, monitoring the selected indicators to answer questions using the scientific method will provide biodiversity trends in the ecosystem. Monitoring activities

leads to insights on issues such as those requiring management strategies, for example, the need for protection of threatened or endangered species, or the eradication of non-native invasive species. Monitoring is also used to assess progress made toward meeting a management objective and is an essential component of a successful adaptive management program.

Introduction

Natural resource managers and other decision makers working at the conservation and development interface confront challenging environmental issues that require science-based understanding of the status and trends of habitats and species. The primary role of the BMAP is to improve natural resource management and conservation and to build institutional knowledge. BMAPs are also designed to determine status and trend monitoring of species and habitats or baseline monitoring that is not focused on a particular management action but aims at increasing our understanding of natural processes and also acts as an early warning system. Reports and recommendations to managers based on the sampling design and data collection are the principal products of the BMAP. Sound data management is necessary to provide quality

information to long-term programs. Sound BMAP programs provide information that managers need to make decisions either alerted to an impending problem, for example, early detection of invasive exotic species or pathogen, or in response to management actions that they are implementing, for example, effectiveness of invasive exotic plant management efforts, or effectiveness of restoration of degraded habitats.

BMAP Spatial and Temporal Scales

Effective BMAP frameworks require successful integration of different monitoring components to produce information that is more useful than the individual components. This integration requires spatial and temporal considerations at the ecosystem and landscape levels.

Monitoring ecosystem structure and function at the landscape level requires careful consideration for the selection of appropriate indicators. The monitoring strategy will utilize several individual indicators that collectively will measure the status and changes within the entire ecosystem. An ecosystem can be very large and most monitoring programs, depending on their design, can only make inferences to the areas that are considered as part of the sampling strategy. Results may be representative of larger areas but must be used cautiously. Often a suite of indicators is selected at various hierarchical levels of ecological organization, such as community, population, genetic levels (Noss, 1990) or from species or habitats of conservation concern and of value to society. Integration of spatial information requires the establishment of measurements made at different areas and scales within the study areas. This strategy requires understanding of spatial sampling design frameworks.

Timelines for sampling indicators also need to be considered based on the characteristics and temporal variations that these indicators may show. For example, monitoring forest dynamics and regeneration often requires 5-year measurements of tree size classes and their distribution in permanent plots, whereas water quality may require continuous measurements. The integration of monitoring programmatic activities requires coordination and communication among BMAP management organizations and other stakeholders to promote wide participation in the use of the resulting information.

BMAP Goals and Objectives

The purpose of BMAP is to develop science-based information on the current status and trends in the composition, structure, and function of habitats and species, and to link that information to management practices and policy decisions. Scientifically based information from BMAP increases the confidence level of a manager in predicting the outcome of his decisions and to operate more effectively. The overall goals of the BMAP are site specific and related to the issues and concerns addressed by the program.

Overall goals and objectives of BMAP include:

- Assess species and habitats to determine presence and relative abundance.
- Select the species and habitats that will be used as surrogates for the area under study.
- Establish the status and trends of selected species and habitat indicators to allow managers to work more effectively to minimize potential impacts on the resource and provide adaptive management strategies.
- Provide early warnings on the condition of species and habitats to help management in developing mitigation strategies.
- Monitor selected species and habitats to understand their natural and human-induced dynamics and conditions. First assessment should serve as a baseline reference to determine desired state.
- Integrate the BMAP in an adaptive management cycle for planning, management, and decision making.
- Provide data-driven information to understand the dynamics of species and habitats through comparison with similar natural and human-managed systems.
- Generate information to meet regional, national, and international environmental laws and regulations.
- Provide timelines and deliverables toward achieving the specific goals of the BMAP.
- Disseminate information generated by the program to multiple stakeholders to engage them in management and conservation efforts.

Based on these goals, it is important to develop a conceptual ecosystem model to define the study areas, identify geographical issues, habitats and species, and describe the ecosystem structure. Designing the assessment and monitoring programs requires the selection of indicators to monitor, and the development of the monitoring protocol. The final components are the implementation of the protocols, synthesizing information, and the application of recommendations as part of the adaptive management process (Figure 1).

The BMAP is based on the scope of the project, specifications to meet the established goals and contain variables that can be measured so that the information collected addresses questions and hypothesis. Managing objectives provides the appropriate focus to address the change/trend objective, for example, to increase the density of Species A by 30% or decrease the frequency of invasive species by 30% at a particular location (Elzinga *et al.*, 1998).

Sampling strategy is based on the sampling objectives of the BMAP that will address the monitoring questions. These questions may be formulated as part of the process and lead to other projects using experimental design to test hypotheses. They include levels of precision and magnitude of variation expected to be detected by the BMAP (see the BMAP protocol design section). The BMAP objectives provide additional details about the monitoring program or sampling protocol and the limits of the program. For example, are the objectives measureable and achievable? Is the monitoring and sampling location specific enough? Are the species and habitats being monitored, clearly selected, and specified? Will the data and information user be able to anticipate what the data and information will look like? Table 1 provides some specific examples of monitoring objectives for BMAP sampling protocols.

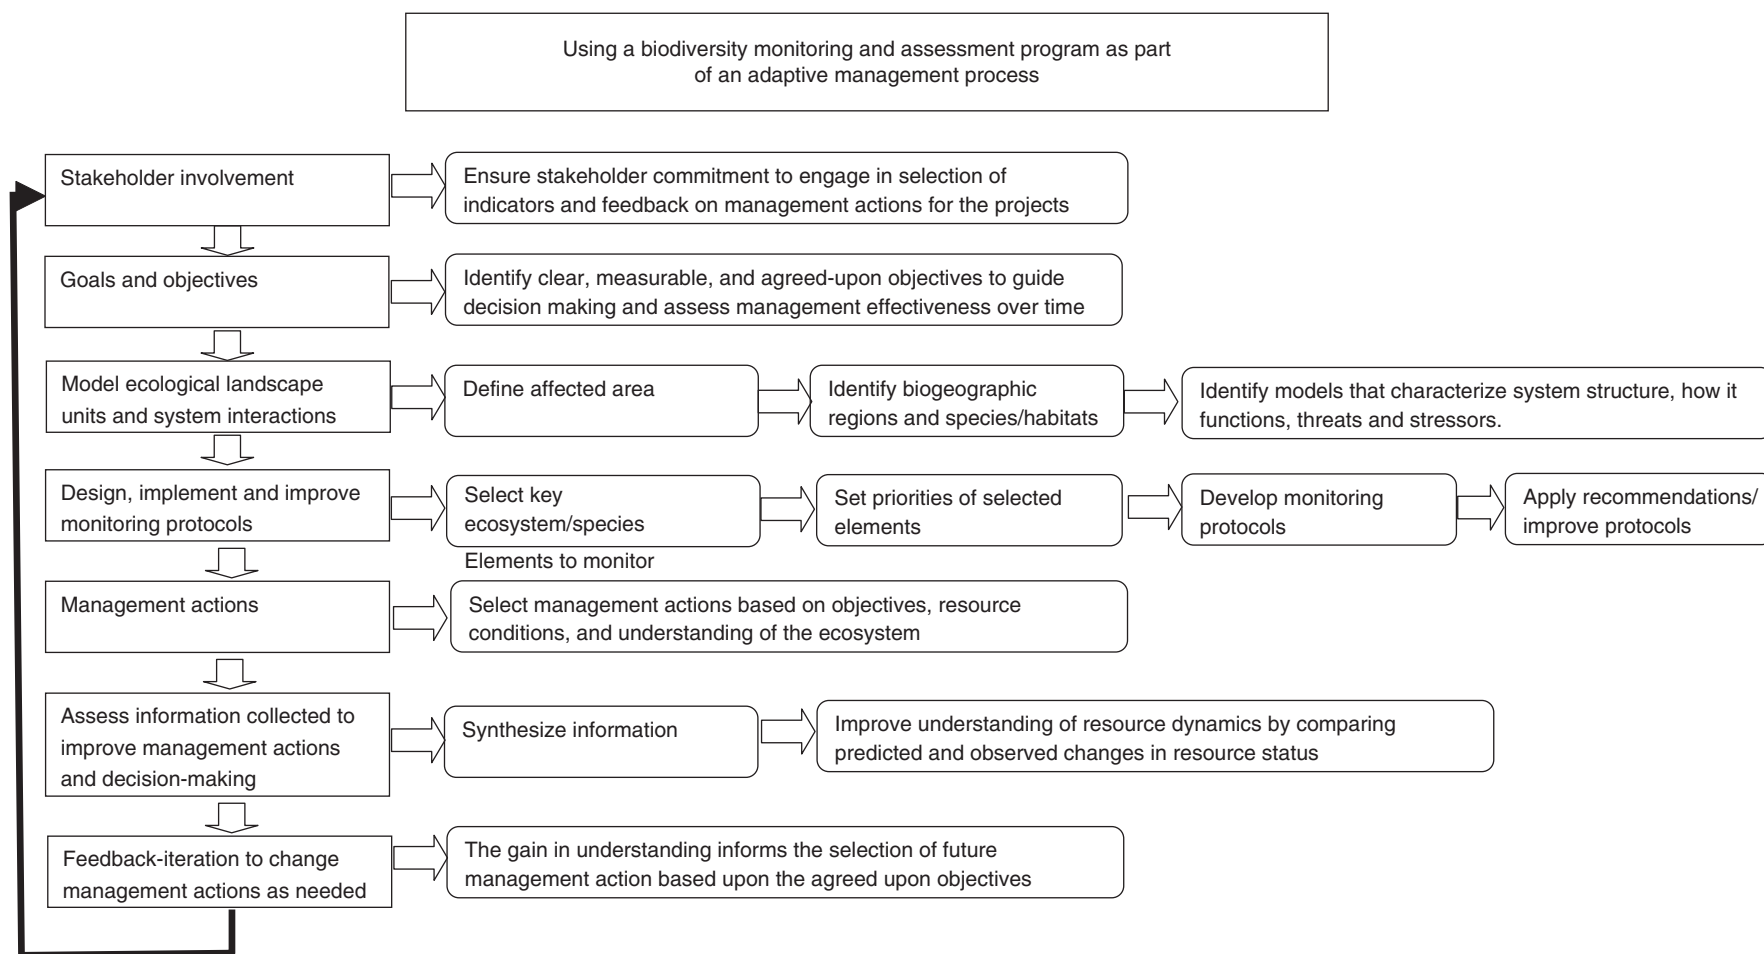

Figure 1 Biodiversity monitoring and assessment program as part of an adaptive management process.

Table 1 Examples of BMAP monitoring objectives

<i>BMAP protocols</i>	<i>Measurable objectives</i>
Wetland vegetation	1. Determine if species composition and abundance is different in areas up-stream and down-stream from park road. 2. Determine if species composition and abundance is the same in areas around the road where road improvements were made.
Fishes	1. Determine fish species diversity, composition and abundance in high altitude freshwater lagoons. 2. Associate these parameters to water quality in areas close and far from access roads. 3. Determine trends in the distribution and abundance of native species of fishes in areas where exotic species are introduced.
Birds	1. Determine annual status and trends in territory occupancy of cloud forest birds in areas near and far from the human development. 2. Determine annual status and trends in nest success of endemic species of birds in areas near and far from the human development.
Bats	1. Determine the distribution and abundance of desert bat species in the coastal pacific desert area of a National Park. 2. Determine short- and long-term trends in the presence of bat species and flower and fruit production by cacti species in the area.
Squamata	1. Determine the species of lizards that are found in the area of influence of new road and infrastructure development. 2. Determine the distribution and abundance of lizards in the area of new road and infrastructure development. 3. Evaluate the mitigation measures and the short and long-term trends of the distribution and abundance of lizards in the restored right of way of new road and infrastructure development and in areas control.
Amphibians	1. Determine the species of amphibians that are found in the area of influence of new development. 2. Determine the distribution and abundance of amphibians in water bodies that are close and far away from the new development. 3. Evaluate the presence of the chytrid fungus in the populations of amphibians close and far away from the new development. 4. Determine the short and long-term trends of the distribution and abundance of the chytrid fungus.
Grasslands bio-restoration	1. Determine the composition and abundance of grassland communities. 2. Monitor short and long-term trends in species composition and abundance of grass land species in areas that have been restored to reduce road erosion.
Endemic tree species	1. Determine the distribution and abundance of the endemic tree species with respect to the area of influence of development. 2. Determine the short- and long-term trends in annual recruitment.
Benthic marine community	1. Determine short- and long-term trends in percent cover of sessile marine benthic invertebrates and algae around a new jetty. 2. Determine short- and long-term trends of non-native marine communities that may have been brought by incoming boats.
Marine fish	1. Determine long-term trends in the composition and abundance of fish species of importance to the local communities in areas close to a newly constructed jetty and its area of impact.

BMAP Guiding Principles

The BMAP is based on the following guiding principles: (1) science-based, (2) peer reviewed protocols, (3) biological sampling, (4) link species/habitat to management objectives, (5) focus on species/habitats of conservation concern, (6) comply with national and international regulatory frameworks, and (7) communicate findings and implement recommendations. A small suite of indicators (Simberloff, 1998; Zacharias and Roff, 2001) are part of the basic measures of the BMAP, including biological (e.g., key species abundance and distribution), physical, and chemical elements and processes (e.g., precipitation, water temperature and pH) that represent the entire array of ecosystem features. These features, when measured over time, reflect temporal and spatial changes in habitat and species related to ecosystem structure and function. They also serve as 'leading indicators' of system integrity, stability, and capacity for self-renewal.

Choosing Appropriate Indicators

According to the U.S. National Academy of Sciences (2000, p. 1) the purpose of indicators and monitoring is succinctly described as:

Developing indicators and monitoring them over time can help to determine whether problems are developing, whether any action is

desirable or necessary, what action might yield the best results, and how successful past actions have been. To develop and implement sound environmental policies, data are needed that capture the essence of the dynamics of environmental systems and changes in their functioning.

Sampling all components of biodiversity in a given area is generally an impractical and costly task, but biodiversity surrogates enable monitoring of ecosystem functions (Noss, 1990, 1999). The concept of 'biodiversity indicators' is widespread and a key component of most biodiversity inventory and monitoring systems (Lee *et al.*, 2005). As examples, one might choose an oak tree species affected by gypsy moth defoliation, or a species whose recruitment and mortality is impacted by extended droughts. During the planning stage, it is recommended to identify potential indicator species. Important criteria in selecting indicator species include the following:

- (i) The species, populations, or observed physical or chemical phenomena should be good measures of questions that the monitoring program was designed to answer.
- (ii) The indicators should be able to detect a condition in advance to assist in solving the problem or else they may have a limited role in achieving the monitoring goals.
- (iii) Whenever possible, indicators should be selected for which experimented controls are present (e.g., populations under different management intensities).

- (iv) It should be possible to monitor the indicators within realistic budgets.
- (v) The species should be selected based on their potential for impacting management decisions (e.g., charismatic species are more likely to facilitate management changes than less-attractive species).

Several considerations play a role in meeting these criteria. First, keystone species are those on which many other species may rely at some point in their life cycles. In tropical regions, for example, nectar-feeding bats are considered as a keystone species because the reproductive success of many plant species through pollination depends on them. Key common species are those that are wide-ranging, easily observed and studied, long-lived, and generally occurring at high-population densities (e.g., oak species in the eastern United States). A sudden increase, decline, or disappearance of these species in certain habitats serves as a warning that may require management attention.

Next, species or taxonomic groups that have sensitive life histories may be good indicators for biodiversity monitoring. Amphibians depend on water for reproduction and will be affected by drought or water pollution. Information on amphibian numbers, diversity, sex ratio, age, and size structure will indicate changes that may affect other components of biodiversity. And, monitoring the abundance and diversity of selected tropical frog populations can provide valuable data on the health of those populations, and hence the habitat, from one year to the next.

Finally, key habitats may also be important indicators. For example, the aspen and wet meadow habitats of the Colorado Rocky Mountains in the United States are good indicator habitats because of the species that depend on them.

Legal and Institutional Framework

The BMAP needs to provide full compliance with applicable legal requirements and project commitments (i.e., government, corporate, lenders, stakeholders, others). The principal requirements and commitments relating to biodiversity and monitoring are embodied in the international, national, state and local laws and regulations, specific project, environmental and social impact assessment (ESIA) and environmental and social management plans (ESMP), Ecological Management Plans, Biodiversity Action Plans, International Performance Standards on Social and Environmental Sustainability, and other national and international conventions, standards, and policies.

Conceptual Ecosystem Model to Support the BMAP

Conceptual ecosystem and landscape models provide an important framework to integrate current information and knowledge of an area to identify the important elements of the system, species, processes, dynamics, and conservation issues, facilitate the communication of complex subjects, and demonstrate connections within the ecological system (Gross, 2003). Models play an important role in virtually all applications of structured decision making, whether adaptive or otherwise, by linking potential management actions to

ecological consequences (McGowan, 2011; Moore and McCarthy, 2010). To make informed decisions, it is important to compare and contrast management alternatives in terms of their costs, benefits, and resource consequences. Models typically express benefits and costs in terms of management inputs, outputs, and outcomes through time. Importantly, they allow one to forecast the resource impacts of management.

Development of conceptual models is recommended before initiating the assessment and monitoring programs. This process improves the collective understanding of the system and the models are important throughout the formulation of the BMAP as they provide the scientific framework for the selection of the elements to monitor. Conceptual models are a combination of diagrams and narratives that communicate interactions among ecosystem processes and dynamics, identify links among system stressors and system responses, assist in the selection of assessment and monitoring variables, and communicate the processes to diverse audiences (Table 2).

The recommended process (Gross, 2003) to develop project specific conceptual models includes the following activities:

- Goal setting. The primary goal of the model is to provide a synthesis of the ecosystem dynamics that will help identify the species, habitats, and other indicators that will be monitored. It will also show the relationship between indicators and ecosystem variables. The model also facilitates communication among professional and technical personal and external stakeholders.
- Set boundaries of the system. The model clearly defines the boundaries of the system illustrating the spatial and temporal issues for monitoring and management. It includes the variations of habitats to be assessed and monitored such as altitudinal variations, forest, grasslands, wetlands, and rivers.
- Identify system stressors. Natural and human-induced stressors, such as pollution, road construction, water use, poaching, logging, land-use changes, and many others, impact ecological systems with different intensity. Stressors are these natural or anthropogenic physical, chemical, or biological impacts to a system that are applied to the system at extreme or deficient levels (Barrett *et al.*, 1976). It is important that the model communicates the relationship among stressors, environmental responses, and the characteristics of the ecosystem. During the process of evaluating this relationship it is important to record the possible assessment and monitoring questions as well, and alternative hypotheses to be considered by the program. It is also important to prioritize, at this time, the list of possible indicators for the BMAP.
- Model reviews and revisions. As new information is generated and goals change over time, the model will need to be revised and updated.

Design Monitoring Protocols for Species and Habitats

Assessment and Monitoring Components

Biodiversity assessment involves compiling inventories and providing baseline information for the selection of the

elements to monitor. These assessments can be comprehensive for multiple species and habitats or selective to target individual or group of species and habitats. The assessment can aid in identifying species, habitats, and communities that are important due to their rarity or those that could be used as

biological indicators, or those that are important to local human communities. This helps determine species and areas that require conservation or restoration actions. The assessment process includes literature reviews, field surveys, stakeholder consultation, and inventories to gather data relevant to the site-specific monitoring program, and to identify knowledge gaps and target indicator variables (Fancy *et al.*, 2009).

Before monitoring or management activities are implemented, an assessment process should be conducted. The assessment consists of an inventory of species and resources in the area of interest, as well as an evaluation of the priorities and threats to those resources. For example, acid deposition is a stressor that can influence both terrestrial and aquatic systems in the mid-Atlantic region of North America and land-use change can increase fragmentation and alter ecosystem processes in the lowland rainforests of eastern Brazil. Without an understanding of the potential effects of stressors, it is difficult to evaluate the best management options and define the indicators that we need to monitor. Stakeholder consultation from subject matter experts is integral to this process to ensure clear understanding of effects, processes, and potential outcomes.

Assessment objectives generally include information on the location, the taxonomic groups, species or indicator to be recorded, attributes to be measured, the desired state of the species or habitat, and any measures on the status to be evaluated. Monitoring objectives also include the management action, threshold values, levels of change occurring before management activities occur, the measurable quantity, direction and degree of change expected from the management, and a time frame for the monitoring activity. As the sampling design is developed, a sample objective is stated that includes specifics such as the size of the change you aim to detect and levels of precision. Before objectives are finalized, stakeholders should be consulted and a thorough review of relevant literature and background knowledge of the study ecosystem and processes should be completed.

Selecting the elements to assess and monitor can be complex and challenging. The evaluation process requires the identification of the reliable measurements that will generate the best species and habitat information for the least cost. It will also require identifying the measures that will be essential to provide early warnings of conditions that require management intervention. The conceptual model described above helps to break down these diverse and complex elements of the system into categories to simplify the task and assure that all critical elements are considered. The study area may be divided into an exhaustive list of mutually exclusive categories geographically, climatically, ecologically (life zones), or by scientific disciplines (geology, hydrology, climatology, biology). More commonly, most of the monitoring programs are organized around scientific disciplines as practical and cost effective approach to engage experts and trained specialists to implement the BMAP (see Table 2).

BMAP Selection Criteria

Selection criteria of habitats and species and associated parameters to be measured for each are essential first steps after

the development of the conceptual model. The selection criteria include: (1) a broad array of species representing a wide array of ecological roles; vegetation, herbivores, long-lived and short-lived species, and mobile grazers and predators; (2) species and habitats representative of common and dominant ecosystems; (3) species and habitats of conservator concern and special legal status such as threatened or endangered species, endemic species, invasive or alien species and species of social, economical and cultural importance; and (4) abiotic parameters, such as sea temperature, precipitation, and meteorological measures are also complementary important criteria to the biotic system. Based on the information from the baseline assessments, the selection criteria for the BMAP is often based on site-specific priorities such as landscape changes; habitat destruction, overhunting, overgrazing, soil compaction, erosion, degradation of water quality, and the conservation status of certain species and habitats.

BMAP Protocols Design

A key component of a credible monitoring program is the protocols for data collection (Holthausen *et al.*, 2005). A protocol establishes how data are to be collected at each sample point. Protocols are detailed plans for each stage of the monitoring process and should be developed based on the management and monitoring objectives (Atkinson *et al.*, 2004; Oakley *et al.*, 2003; Szaro *et al.*, 1999a). Protocols are necessary to ensure that changes detected from the monitoring data reflect actual changes in the environment and are not just a result of measurements taken by different observers using slightly different methods or approaches. Well-designed protocols allow comparisons of data between organizations and localities, and lend credibility to your program during peer-review processes. Protocols should be developed for all steps of the monitoring project, including sampling design, field methods, personnel training, data management, quality assurance and quality control, data analysis, interpretation, and reporting. The US National Park service has an online database of existing protocols that are available for download: <http://science.nature.nps.gov/im/monitor/VitalSigns/BrowseProtocol.aspx>.

Monitoring and assessment protocols are designed to frequently collect and analyze observations of selective elements of the system to evaluate the status and changes of these elements and the resource and to measure progress toward meeting the goals and objectives of the BMAP (Oakley *et al.*, 2003; Elzinga *et al.*, 1998). Precise monitoring and assessment protocols are necessary to measure variables and observations in time by different individuals. Protocols often include quality assurance and quality control measures to ensure that they are being implemented correctly and to provide the levels of confidence for the credibility of the program, which allows comparisons of data across space and time sampling intervals.

It is often useful to pose the following questions related to the variables to measure: Are the results of each specific technique well integrated with the overall program? Do the methods that are used ensure reliable, timely, and effective data analysis? Are the collected data subject to the appropriate techniques for data management and analysis? Could the data gathered be coupled with new technologies for analysis and

management? What mechanisms exist or can be developed to allow timely transfer of data and information to managers and decision makers?

Oakley *et al.* (2003) provides the guidelines for the preparation of long-term monitoring protocols that include the Standard Operating Procedures that specifically describe how all the components of the monitoring program will be carried out. Periodical formal reviews of individual protocols and the monitoring program are an important component of the overall quality assurance of the program.

Developing the Sampling Design

Fundamentals

Sound sampling designs provide guidelines for the most cost-efficient and effective way to gather and analyze data while maintaining high quality control standards (Smyth and James, 2004). The sampling design should address the following questions: (1) What do researchers need to know about the study area (e.g., data on forest composition, structure, and diversity as well as site-specific information such as the effects of acid deposition, drought, fires, or other disturbances)? (2) How will data from the program be used (managerial and scientific uses)? (3) Is the site representative of the habitat of interest? (4) Will the design be sensitive enough to detect changes? (5) What limits of change are expected and are important to detect (e.g., mortality rates of forest stands should not exceed 3–5% per year)? (6) What is the degree of confidence expected from the results? (7) Will the sampling design produce results that will be representative of what is happening in the entire study area?

Sampling Objectives

Sampling objectives should be developed in conjunction with management objectives (Elzinga *et al.*, 1998). Sampling (or statistical) objectives specify information such as target levels of precision, power, and the magnitude of change that one wants to detect. Precision is a measure of repeatability, or how close two repeated measurements are to each other, and is frequently obtained by calculating the standard deviation of the estimated mean from which confidence limits are calculated. Sampling objectives also identify the level of change to be detected and the risk of missing a real change or, alternatively, detecting a false change. These factors are related to the variability of the population and the number of samples used, all of which will determine the power of the sampling approach. The sampling objective should also define the population of interest. This target population consists of the complete group of sample units (e.g., individual animals and quadrats), about which inferences are to be made. It is important to distinguish the target population from the population actually sampled (the sample population). Statistical inferences can only be made about individuals and areas that have a chance of being sampled. For example, the target population may be all individuals of a specific ant species within a reserve. However, if sampling to the roadside is limited, then the ants in areas close to roads become the sample population and inferences can only be made about ants inhabiting areas close to roads. In some cases, it may be

necessary to define a new sample population for logistical reasons, but this can be done in such a way that the inference is not reduced. For example, if the target population covers a very large geographic area, sample sites need to be randomly placed within the target population and sampling should be done only within these. As the sample sites have been randomly placed within the target population, inference still extends to the entire target population.

Defining Spatial and Temporal Scales

Identifying the spatial and temporal scale of the study is essential at the planning stage because it has important implications in defining effective sampling design and resource requirements. The scale often depends on the scientific goals of the program or on the managerial regions under study. Often, the scale for assessment and monitoring is based on the geographical boundaries of the protected area or conservation unit, or on subsets of such areas. Biodiversity assessment and monitoring at local and regional levels can provide decision makers with high-quality data and cost-effective choices. At local levels, studies usually concentrate on specific communities, and are chosen because of the degree of threat, because of species' locations, or due to organizations' legislative boundaries; but the results may not be representative of the landscape-level biodiversity. Monitoring populations at the landscape level provides broader information sets, but often requires sampling under different land management conditions, and may call for special permits and a large budget. The time frame depends on the biology of the species (e.g., short-lived species will respond more quickly than long-lived ones), the intensity of management (intense management produces rapid changes), and the level of specified change (the smaller the change, the sooner it will be detected). Short-term responses may benefit from more frequent evaluation of the management objectives, and results can be presented relatively fast. Nevertheless, sufficient time must be allocated to detect changes as many impacts may not be detected until as much as a decade after the initial activity. Conclusions were obtained only after a few years indicating that no effects of management could be deceptive. In some cases, monitoring objectives may be best met by focusing on more than one scale. One approach for answering multiscale questions is to select indicators at multiple hierarchical levels of ecological organization (e.g., genetic, individual, population, community, and landscape). Using multiple indicators can also increase knowledge gained as each indicator may respond differently to the same stressor or management activity. Integration of these levels will often require nesting of more intensive and frequent sampling within the context of less-frequent sampling. Objectives with multiple time frames also benefit from frequent assessment of monitoring directions and protocols within the context of long-term goals.

Parameters and Sampling Unit

- *Choice of parameter:* A parameter is a measurable attribute such as plant height or animal mortality. The parameter should be sufficiently sensitive in detecting the desired level of change and capable of distinguishing between natural fluctuations and human-induced change. The

change registered by the parameter should be biologically meaningful and lead to a logical management response. The variability in observer error inherent in measuring the parameter should be minimal. In addition, the cost of measuring the variable must be within the budget, and it is necessary to identify the expertise and technical ability needed to measure the parameter. Some of these issues may be addressed by conducting pilot studies.

- *What is a sample unit?* A sample unit is often determined by the choice of parameter. For example, if the parameter is a plant part such as the number of flowers per plant, then your sample unit will be the individual plant. If your parameter is plant density, a quadrat will be the appropriate sample unit choice. Important considerations in choosing sample units include independence from each other, randomization in sample unit selection, and sufficient replication (sample size) of units (Elzinga *et al.*, 1998). When this is the case, statistical estimates of your parameter can be produced along with a reliability estimate. Randomization of the selection process is imperative to produce unbiased information with inference to the population as a whole. Selectors of sample units, based on judgments of 'representative' areas, are often heavily biased.
- *Sampling unit size and shape:* Some sample units have pre-determined unit sizes (e.g., individual lizards), and thus the unit sizes and shapes are not factors in the design. Others, such as pitfall traps, could be set at any unit size or shape that the design dictates, and are thus determined by the researcher. As increasing sample sizes (i.e., the number of samples) increases the power to detect changes, smaller sample units may be advantageous by allowing the sampling of more units. However, if the units are too small, the sample will be highly variable, reducing the precision of the estimates. Conversely, in very large plots, the variability among units will be low, but there may be too few plots to compare. This is also dependent on the inherent variability in the community or population being monitored. If the variability in your sample is low, then you may be able to achieve the same power to detect changes with fewer and smaller sample units, than if the variability is high. In plot-based sampling, the shape of the plot must also be determined. Rectangular plots have a greater "spread" over the area than square or circular plots, and are thus more likely to incorporate individuals if they are clumped or aggregated. This decreases the variation among the plots and increases the precision of the estimates.
- *Sampling unit locations:* Positioning of sample units within the population should be done in such a way as to (1) incorporate a random component to the selection process and (2) achieve good interspersed of units across the population. There are a number of different types of sampling methods that can be used; the most common ones being the following:
 - a. Simple random sampling can be employed for relatively small study areas with homogenous habitats. This type of sampling keeps analysis simple, but it may lead to some areas within the target population being under-represented. It tends to be an inefficient design for clustered populations, and it can be logistically difficult

- as it can result in considerable travel time between sample units in larger study areas.
- b. Stratified random sampling is useful when the parameter of interest is influenced differently across some variables such as habitat or climatic differences. A simple random sample is taken within each stratum, and the number of sample units within each stratum does not need to be equal. For example, if the strata are of differing sizes, the number of units per stratum may be proportional to the size of the strata. If there is a strong influence on the parameter by the strata variable, this design can result in more efficient population estimates than simple random sampling.
 - c. Systematic random sampling, when samples are placed in a grid or regular pattern, is useful for most sampling situations, except when the number of possible samples is low. It provides good interspersions of sample units and is an efficient design for data collection. Two necessary components of this design are (1) a randomly selected starting point and (2) units that are far enough from each other to be considered independent. Another approach, generalized random tessellation stratified (GRTS) sampling, combines random and systematic sampling in a spatially balanced design allowing for addition or subtraction of sample sites/units in the future while still maintaining spatial balance.
 - d. Restricted random sampling is setup by determining the number of sampling units that are needed (n), and then dividing the population into n equal-sized segments. A single sample unit is randomly positioned or selected within each segment. This method provides good interspersions across the population and is an alternative to systematic sampling if the number of potential samples is low. When the potential number of samples is 425–430, systematic sampling is more efficient and should be chosen instead.
 - e. Cluster sampling is used when it is difficult to take a random sample from the population. Clusters of units are identified, and then clusters are randomly chosen instead of randomly choosing from the units themselves. Every unit within the cluster is then measured. This is a cost-efficient design but more complex calculations are required.
 - f. Two-stage sampling can be used in place of cluster sampling if there is a large number of units within each cluster. In two-stage sampling, a second sample of units is taken within each cluster, instead of sampling all the units in the cluster. Cluster sampling and two-stage sampling are generally the only efficient methods for estimating a parameter associated with individual plants.
 - g. Should permanent or temporary sample units be used? As monitoring occurs over time, it is necessary to decide whether to measure the same sample units at each time period, or to randomly reselect sites at each time period. This decision partially depends on whether the aim of the project is to estimate the status or the trend. If the main goal of the program is to determine the status of a population, selecting a new sample is appropriate. Conversely, if the objective is to estimate the change or trend in a population, it is best to use permanent units. Permanent units outperform temporary ones for trend assessments, as statistical tests for detecting change between one time period and the next are more powerful when based on permanent units owing to the removal of variation between different plots. However, permanent units are often more costly as units need to be marked for relocating at later time periods, and marking may be infeasible and difficult (e.g., sand dune systems). As monitoring programs often aim to determine statuses and trends, an option is to incorporate both aspects into the design. For example, an augmented rotating panel design includes some units that are resampled every year and others that are reselected on a rotating basis. Another option is the augmented serially alternating design in which some units are always sampled and the others are sampled on a rotating basis. However, data analysis becomes more complex with these designs, and this fact should be taken into account during the planning stage.
 - h. How many sample units do we need? A sufficient sample size gives you the power to assess whether your management objective has been achieved. However, as costs increase with your sample size, a balance needs to be met. There are a number of issues involved in determining the appropriate sample size. The initial consideration is the level of precision stated in the objectives. For example, if the objective is to increase the population abundance of a species by 20%, a sample size with sufficient precision to detect a change of that magnitude is needed. It is important to keep in mind that the increase in precision is not proportionate to the increase in sample size. The statistical benefits of increasing sample size generally diminish after a certain sample size has been achieved. There are a number of power analysis equations that can be used to determine sample size, and, for these calculations information (such as variability in the measurements) needs to be gathered during a pilot study. Researchers need to be familiar with the assumptions of these formulas and the effects they have on the calculations before proceeding. Assumptions include random selection of sampling units, an infinite population, and an approximately normal distribution of sample means.

Data Analysis

Once the scientific questions are defined and the objectives of the monitoring established, the methodology for the data analysis needs to be considered. Each monitoring protocol contains detailed information on analytical tools and approaches for data analysis and interpretation, including the rationale for a particular approach, and advantages and limitations of each procedure. A number of graphical methods are used to reveal patterns in the data that are not evident by calculating summary statistics such as means and standard deviations (Ellison, 2001). The type of data analysis that is most appropriate should be determined during the planning

stage of the project. Analysis will depend on the objectives and design.

Exploring Data

The first important step in data analysis is to do an initial exploration of the data. This is very important when assessing pilot studies as it will help in understanding the variability in the data as well as whether the assumptions of the parametric tests apply to the data (*see* Parameter Estimation and Significance Tests). There are a number of graphical methods that reveal patterns in the data that are not evident by calculating summary statistics such as means and standard deviations (Ellison, 2001). A normal probability plot allows you to assess how closely the data fits a normal distribution. The observed values are plotted against the values that would be expected if the data came from a normal distribution. A plot showing a straight line indicates normality. Density plots such as histograms are useful for displaying the distribution of data and thus can reveal issues such as data skewness. However, histograms have the disadvantage of grouping the data into arbitrarily determined bars or bins. The number and width of these bins can alter the shape of the histogram. Dot plots are similar to histograms, where all data points are presented. Box plots are another commonly used form of data exploration. This plot displays more information about the data than a histogram. The median, 25th and 75th percentiles, data spread, and outliers are represented.

Parameter Estimation and Significance Tests

The type of data analysis that is most appropriate should be determined during the planning stage of the project. Analysis will depend on the objectives and design. For example, parameter estimation is generally needed for a monitoring project with target/threshold objectives, and significance tests are often used in projects with change/trend objectives. Parameter estimation involves generating a sample statistic such as a mean or total that estimates the true population value. An associated confidence interval is also calculated. This provides an estimate of precision around the sample statistic that specifies the likelihood that the interval includes the true value. The sample statistic can then be compared with the target or threshold value to assess whether the objective has been reached or if further management activity is necessary. For example, the management objective is to maintain a population of at least 5000 individuals of a certain species in a reserve over a period of 10 years. If the lower bound of the confidence interval is above this threshold, there is confidence that the objective has been achieved (based on the desired confidence level). Conversely, if the upper bound of the confidence interval is below the threshold of 5000, there is confidence that the objective has not been achieved. The results are less clear when the confidence interval overlaps the threshold. In these cases, management decisions are often based on the perceived level of risk associated with implementing or not implementing further action. Tests of significance are used to assess whether there has been a change in the parameter of interest between the time periods of the monitoring program. In the same way, they can also be used to compare specific parameters in different spatial areas. These tests produce a probability estimate of whether a change seen

is real or simply due to random variation from different samples. The next step is to test for significance and thus a null hypothesis needs to be expressed. This usually asserts that there has been no change in the parameter of interest. The hypothesis will be rejected if the significance test concludes (with a desired level of confidence) that there has been a change in the parameter between the sampling periods. The null hypothesis is evaluated by calculating a test statistic that quantifies the difference between the samples. The confidence level is important as this determines, on a probabilistic basis, how large the test statistic should be before the null hypothesis is rejected. There are two types of errors that can be made in arriving at a decision regarding the null hypothesis. The first, Type I error, involves rejecting the hypothesis when it is actually true. The larger the predetermined confidence level, the more likely it is that the null hypothesis will be falsely rejected. The second, Type II error, involves failing to reject the null hypothesis when it is actually false. Type II error is related to the power of your test. The most commonly used significance tests for monitoring questions are *t*-tests (when comparing two samples), analysis of variance tests (when comparing more than two samples), and *w*² tests (when comparing proportions). The first two tests here are parametric tests as they estimate population parameters such as means or totals. Parametric testing requires several assumptions to be met for the results of the test to be valid: (1) The population must follow a normal distribution. (2) The variances must be relatively similar between the samples. (3) The sample must be randomly selected from the population. There are tests that evaluate departures from assumptions 1 and 2, but in most cases graphical review of data is the best method. If deviations from these assumptions are found, increasing sample size or transforming data may resolve the issue and allow you to proceed. If not, there are alternate methods (nonparametric statistics and resampling methods) that do not require these assumptions to be met.

Nonparametric Statistics

When the assumptions of parametric tests cannot be met, or due to the nature of the objectives and data, nonparametric statistics may be an appropriate tool for data analysis. Many nonparametric tests focus on the order or ranking of data, not on the numerical values themselves. Other nonparametric tests are useful for data for which ordering is not possible, such as categorical data. These tests generally focus on the differences between samples in medians instead of their means, as seen in parametric tests. Nonparametric tests commonly used for monitoring questions are *w*² tests, Mann-Whitney *U*-test, Wilcoxon's signed rank test, and McNemar's test. The advantages of nonparametric tests are (1) they may be the only alternative when sample sizes are very small, unless the population distribution is known exactly, (2) they make fewer assumptions about the data, (3) they are useful in analyzing data that are inherently in ranks or categories, and (4) they often have simpler computations and interpretations than parametric tests. The main disadvantage of nonparametric tests is that they are generally less powerful than their parametric analogs.

Data and information management goes hand in hand with data collection. The raw data are the basis for the

analysis, synthesis, and modelling of the monitored species and habitats that will generate the interpretation for decision making. For these reasons, data need to be properly recorded, analyzed, reported, archived, documented, and catalogued using a proper information management system. Data management within the information management system needs to ensure that the data are readily available, unverified data are not released, data distributed is accompanied by metadata, sensitive data (i.e., potential commercial value of plant species) are identified and protected from unauthorized access, and data dissemination records are maintained.

Decision Making

Analysis and evaluation elicit answers to the questions underlying the project's objectives, thus allowing for the generation of management recommendations and the calibration of the program. In addition, it allows an evaluation of the process. It is often useful to pose the following questions: Are the results of each specific technique well integrated with the overall BMAP? Do the methods used ensure reliable, timely, and effective data analysis? Are the collected data subject to the appropriate techniques for data management and analysis? Could the data gathered be coupled with new technologies for analysis and management? What mechanisms exist or can be developed to allow timely transfer of data and information to managers and decision makers? Management approaches should be viewed as a means to reach operational goals. Through evaluation of the monitoring data, managers receive timely feedbacks as hypotheses are tested. Thus, evaluations are the tools for improving management by checking on management actions and providing guidelines for improvement. For example, when a predetermined degree of change is detected, appropriate action is taken and the results are evaluated. All the preceding steps lead to decision making regarding the need or lack, thereof, to adjust the management practices and monitoring program. If the findings determine that biodiversity trends are within the expected values, monitoring will continue without substantial alterations. If significant changes in the trends are observed, managers or decision makers need to design the most appropriate response in an adaptive management framework. The reasons for monitoring can be evaluated at this stage. Is the monitoring still required, and, if so, do the objectives still remain the same? Inconclusive results require adjustment of the objectives and sampling approaches to increase the degree of precision. Therefore, careful planning and design of the monitoring program can reduce the risk of inconclusive information.

Data and Information Management

Analysis of the data generated by the BMAP will support the program objectives, the sampling design, and the information for management and stakeholders. There are several levels of data analysis generated by assessment and monitoring protocols: (1) descriptive summaries of basic statistical analysis; (2) baseline descriptive information on status of the monitored resource; (3) trends and condition of the monitored resource; and (4) statistical synthesis of resource trends along spatial and

temporal scales. Often descriptive analyses are performed at any time following data collection and input to calibrate sampling methodologies and detect early variations. One approach is to ensure that results are reported on a regular basis – may be annual or less frequent depending on the protocol. The idea is that data is put out in some form to stakeholders. These more frequent reports are low level data summaries. Status and trends reports go into more depth and involve more review, but are less frequent. A long-term trend information synthesis is subject to scientific peer review as appropriate.

The US National Park Service (2008) has provided Data Management Guidelines for Inventory and Monitoring Networks: http://science.nature.nps.gov/im/datamgmt/standards/data_standards_summary_20100610.pdf. In addition, national (NPS, 2008) and network data management plans (e.g., Callahan and Wakamiya, 2008) are developed and made available. The strategy for data and information management for BMAP includes: describing the long-term data and information management for the BMAP with the overall BMAP goals and strategies; defining the specific procedures and work practices for effective data management; training the BMAP personnel in sound data management practices; encouraging effective data management practices as a part of project management so that all data are available and usable for management decisions at all times; and promoting data sharing, software development, applications and analyses. The products that are often part of the data and information management system include:

- Compiled data – GIS information, maps, species lists, data files, and analyzed records.
- Documents – BMAP protocols and protocol updates, metadata, information on reference collections and photographs.
- Reports – Periodical or final reports and publications.
- Management and administrative records – BMAP contracts and agreements, BMAP operational timelines, research permits, and memorandum of understandings.

Information Management Goals

The information management goals for the BMAP are: (1) to confirm that the BMAP personnel leading the protocols, data collection and data management, and collaborators understand the essentials of data and information management; (2) to implement effective data management practices by integrating quality control procedures throughout the project; (3) to generate communication protocols to reach multiple stakeholders; and (4) to develop a framework to integrate the monitoring information into recommendations that can be implemented by adaptive management.

Communications

Communicating the BMAP results is essential to disseminate knowledge about the resource and its management, and to keep stakeholders informed of the activities performed by the program. There are many approaches to develop communication plans including the establishing of mechanisms and timing for information dissemination, developing the information and tools to convey the messages to specific audiences,

creating timelines for knowledge and information dissemination, assessing the cost to implement the communication plan, and defining the messages to be communicated to each audience.

BMAP and the Adaptive Management Approach

Adaptive management is a systematic and iterative approach for improving resource management by emphasizing learning from management outcomes (Holling, 1978; Bormann *et al.*, 2007). The underlying assumption is that adaptive management is not simply changing management direction in the face of failed policies but is a planned approach to reliably learn how to improve policies or management practices over time in the face of uncertainty (Bormann *et al.*, 2006, 2007; Burgman, 2005). Adaptive management is not an end in itself, but a means to more effective decisions and enhanced benefits through monitoring the impacts of management practices at achieving the desired outcome. A fundamental premise of adaptive management is that complete knowledge of species and ecological systems is not only incomplete but almost impossible to fully determine (Stankey *et al.*, 2005). As a result, there is a growing realization that decisions need to be made without complete understanding and that expanding knowledge through traditional scientific inquiry will always be limited by resources and time. Adaptive management is one way that understanding and learning can directly inform decision-making and policy processes. In the case of biological resources, the desired outcome is to maintain biodiversity in an optimally functioning state. Human activities can have drastic impacts on biodiversity, impacts that often are irreversible or require long and costly periods of recovery. Managing biodiversity conservation through the adaptive management process can help to avoid or mitigate those impacts.

Adaptive management can be described as a cycle of iterative activities, where each step builds on the learning experiences of previous steps, as the calibration of the goals and objectives is conducted through a feedback process determined by assessing and analyzing monitoring data (Figure 1). Each step is calibrated periodically to assure that the appropriate information feeds the next level. The cyclical nature of the process is very important in validating the results of the separate steps. One useful way to describe the implementation of adaptive management is in terms of a setup or planning phase in which its key components are put in place, and an iterative phase in which they are linked together in a sequential decision process (Williams *et al.*, 2009). The iterative phase utilizes the elements of the setup phase in an ongoing cycle of learning about system structure and function, and managing based on what is learned.

Stakeholder Involvement

Project definition, development, and implementation require continuous stakeholder involvement and feedback. Stakeholders are individuals representing local, regional, national, and international communities, agencies, nongovernmental organizations (NGOs), industry, and any other organization with an interest in the project or responsibility within the area

of the project's influence. Consulting stakeholders throughout different stages of the project is very important. Of particular importance is the participation of stakeholders in assessing the resource problem and reaching agreement about its scope, objectives, and potential management actions (recognizing that differences of opinion about system responses may exist even with consensus on these issues). By defining the operating environment of a project, stakeholders directly influence both decision-making and the opportunity to learn. The breadth and extent of stakeholder involvement can vary greatly among projects, and both are influenced by the scale and complexity of the intended project. Stakeholder participation in some cases will be restricted to an internal process when the organizations' goals are driven by legal requirements and institutional/organizational policies.

Management Objectives as Related to the BMAP Objectives

Objectives, resource status, and learning all influence the choice of management interventions in adaptive management. Objectives also play a crucial role in evaluating performance, reducing uncertainty, and improving management through time. It is especially important to have clear, measurable, and agreed-on management objectives at the outset, to guide decision making and assess progress in achieving management success. It is often the case in adaptive decision making that there are multiple objectives. In such a situation it is important to weigh different objectives in terms of their perceived importance, so as to facilitate the comparison and prioritization of management alternatives (Burgman, 2005). Initially, management objectives are formed to frame the question and goal.

Management Actions

Like any iterative decision process, adaptive decision making involves the selection of an appropriate management action at each decision point, given the status of the resources being managed at that time. Resource managers and stakeholders, typically working with scientists, have the responsibility of identifying the set of potential actions from which this selection is made.

The management alternatives in an adaptive management project constitute a key element in its operating environment, and they can strongly influence strategy selection. Just as the choices made in daily life depend on one's available options, so are strategy choices in an adaptive management project constrained by the set of available options. If these options fail to span a reasonable range of management activities or fail to produce recognizable and distinct patterns in system responses, adaptive management will be unable to produce effective and informative strategies. This argues for careful thinking about the potential actions to be included in a project.

Decision-Making

At each decision point, an action is chosen from the set of available management alternatives. Management objectives

are used to guide this selection, given the state of the system and the level of understanding when the selection is made. The appropriate action is likely to change through time, as understanding evolves and the resource system responds to environmental conditions and management actions. That is, management is adjusted in response to both changing resource status and learning. It is the influence of reduced uncertainty (or increased understanding) on decision making that renders the decision process adaptive.

Follow-up monitoring

Monitoring is used to track system behavior, and in particular to track the responses to management through time. In the context of adaptive management, monitoring is seen as an ongoing activity, producing data to evaluate management interventions, update measures of model confidence, and prioritize management options in the next time period.

Evaluation, Decision-Making, and Feedback

At any given time, the gain in understanding from monitoring and assessment is used to inform the selection of management actions (Szaro *et al.*, 1999b). As understanding evolves, so too does the decision making that is influenced by improved understanding. In this way, the iterative cycle of decision making, monitoring, and assessment leads gradually to improved management as a consequence of improved understanding.

Management approaches should be viewed as a means to reach operational goals. Through evaluation of the monitoring data, managers receive timely feedback as hypotheses are tested. Thus, evaluations are the tools for improving management by checking on management actions and providing guidelines for improvement. For example, when a predetermined degree of change is detected, appropriate action is taken and the results are evaluated.

The need to better understand and characterize the process elements of adaptive management often becomes more pressing as adaptive management rolls forward through time. Thus, stakeholder perspectives and values can shift as the adaptive process unfolds, and previously unanticipated patterns in resource dynamics can arise that require an adjustment of objectives, alternatives, and other elements of the process. In this sense, learning focuses on changes in institutional arrangements and stakeholder values as well as changes in the resource system.

All the preceding steps lead to decision making regarding the need, or lack thereof, to adjust the management practices and monitoring program. If the findings determine that biodiversity trends are within the expected values, monitoring will continue without substantial alterations. If significant changes in the trends are observed, managers or decision makers need to design the most appropriate response in an adaptive management framework. The reasons for monitoring can be evaluated at this stage. Is the monitoring still required, and, if so, do the objectives still remain the same?

Inconclusive results require adjustment of the objectives and sampling approaches to increase the degree of precision.

Therefore, careful planning and design of the monitoring program can reduce the risk of inconclusive information.

Learning from Experience

The explicit hypotheses about the relationships between strategies and objectives and the emphasis on learning are some of the basic elements of adaptive management (Price and Daust, 2009). Assessment and monitoring programs are widespread in conservation organizations, agencies, and industry as a means to improve understanding and future management. Many have had mixed results, suffering from problems that may have been foreseen if other approaches and programs had been reviewed (Stem *et al.*, 2005; Reid, 2001). Although each monitoring program has differing objectives and thus needs to be tailored individually, there is much to be learned from previous projects. Common issues include: poorly defined monitoring questions and objectives, poorly trained field crews, incomplete baseline information and assessments, sampling plans that are not designed to meet objectives, delays in analyzing data, inadequate monitoring durations, poor data management and interpretation, and lack of integration of the monitoring results into management. In many cases, utilizing management in an experimental context, such as that implemented in adaptive management, may be the only feasible way to gain the system understanding needed to improve that management.

All these can be overcome by paying greater initial attention in identification of specific monitoring questions, goal development, and project planning. Strict development of protocols for each step of the process increases quality control and allows the identification of potential issues at the outset. A more integrated approach to biodiversity management across sectors, administrative boundaries and at landscape and seascape scales would be an important step forward in conservation (European Environment Agency, 2010). To accomplish this, there is a need for greater collaboration within the conservation community to promote learning from experience, reduce duplication of efforts, and strengthen projects by combining resources.

Glossary

Beta diversity Portion of regional diversity due to differences between local communities in their taxonomic, functional, or phylogenetic composition.

Community assembly processes Processes which influence the assembly of species to form communities – particularly those processes that influence the probability of occurrence and the abundance of species in local communities.

Ecosystem function The rate, level, or temporal dynamics of one or more ecosystem processes, such as primary productivity.

Environmental filtering Constraints on the presence and abundance of species in local communities or regional species pools due to abiotic conditions.

Evenness The equitability in abundance of the species present in a local community or region.

Functional trait space Space where species are located according to their functional traits. Functional trait space may be multidimensional, with each functional trait representing a separate dimension.

Hierarchical partitioning of diversity Process of partitioning regional diversity between alpha (local) and beta components.

Local community Collection of interacting or potentially interacting individuals or species. The spatial scale covered by a local community depends on the scale on which interactions occur.

Niche complementarity Enhancement of taxonomic diversity and ecosystem functioning through differences in functional traits between species that co-occur in local communities.

Regional species pool Species occurring within a defined geographical area or in a collection of samples from within such an area.

Introduction

Biodiversity is a multifaceted concept, and this is perhaps best illustrated through the definition supplied by Gaston (1996) as “the variety of life on Earth at all its levels, from genes to ecosystems, and the ecological and evolutionary processes that sustain it.” Quantification of such a broad concept is obviously challenging, but we cannot begin to understand the causes of biodiversity loss and the consequences of this loss for ecosystem functioning unless we can devise methods for the measurement of biodiversity. The increasing interest in the quantification of functional diversity (FD) arises from the observation that species differ both in their response to disturbance or environmental stress and in their influence on ecosystem functioning. This observation has led to the general realization that traditional measures of taxonomic diversity are inadequate for understanding the relationship between biodiversity, environmental filters, and ecosystem functioning. FD measures provide a means of examining the mechanisms by which functional differences between species influence the response of biodiversity to environmental stress (and disturbance) and the effect of biodiversity on ecosystem functioning. This article provides a definition of FD from which independent measures can be derived, identifies key criteria required for valid FD measures, reviews existing FD measures, and provides some examples of their application.

Defining Functional Diversity

Quantification of functional diversity requires a definition of FD from which measurable concepts can be derived. Many

definitions have been provided by different authors, but these generally do not provide much guidance in deriving FD measures. Most definitions agree that FD is the diversity in the functional traits of the species in an assemblage. However, this general definition contains two terms that need to be clarified further: (1) diversity as applied to functional trait data and (2) which traits are functional traits. For many years, taxonomic diversity has been separated into two independent components – species richness and evenness in species abundance. Mason *et al.* (2005) demonstrated that these components have their analogs in FD (i.e., functional richness and functional evenness), while also identifying a third independent component – functional divergence (Figure 1). They gave a definition of FD as the distribution of the species and abundance of a community in functional trait space, including:

1. the amount of functional trait space filled by species in the community (functional richness);
2. the evenness of abundance distribution in filled trait space (functional evenness); and
3. the degree to which abundance distribution among species maximizes divergence in functional traits (functional divergence).

Defining FD in this way helps to guide the development of measures for its quantification. Each of the components represents a mathematical concept that can be quantified using indices that vary on a continuous rather than a categorical scale. This definition of FD as three independent components also shows that no single index can give a complete quantification of FD. This definition also provides a means for

Figure 1 The primary components of functional diversity. The vertical axes represent abundance (e.g., biomass). The bell-shaped curves indicate the distribution of the abundance of individual species in functional trait space. The vertical dotted lines indicate the amount of niche space filled by the community as a whole. Comparison of the central diagram with those in the corners demonstrates how changes in the distribution of species and abundance in functional trait space affect each component. Functional richness decreases either if the range of functional trait values is narrower (a) or if there is unoccupied trait space between the maximum and minimum trait values (b). Functional richness can decrease without a change in functional evenness or divergence (a). Similarly, functional evenness and functional divergence can increase or decrease without a change in functional richness if the amount of niche space filled is unchanged (c and d). In (c) the increase in functional divergence is associated with a decrease in functional evenness, but these components generally vary independently of each other (see Mouchet *et al.*, 2010). Functional evenness is lower in (d) as the decrease in the evenness of spacing between species causes abundance to become more concentrated at the lower end of the trait gradient and more sparsely distributed at the upper end (thus resulting in a less even distribution of abundance in trait space).

arranging the growing range of published FD measures into a typology. This is helpful for ecologists attempting to choose indices for the quantification of FD in their study assemblages. For a full quantification of FD, a separate index is required for each component. Because indices that estimate the same component are almost always highly correlated, only a single index is required for each component.

Lavorel *et al.* (1997) provide a succinct definition of a functional trait as: “A feature of an organism, which has demonstrable links to the organism’s function.” Most studies seem to conform to this definition, with functional traits considered to be characteristics of individual organisms that act as indicators of functions occurring at the scale of individual organisms, though sometimes the functions themselves are considered functional traits (Violle *et al.*, 2007). Some confusion has been caused by studies that consider properties measured at the scales larger than an individual to be functional traits (e.g., net primary productivity). Violle *et al.* (2007) provide a typology accommodating the variety of senses in which the term has been applied, but this article considers only functional traits measured at the individual scale.

There is a growing body of primary research demonstrating that measureable attributes of individual organisms are linked

to functions at the individual level. These processes might include growth rate, response to environmental stress, the types of resources used, where and when resources are acquired, and how resources are allocated within the organisms. For example, specific leaf area (SLA) is an indicator of maximum rates of growth in plants. Mouth size is an indicator of prey size in fish. Leaf tissue density indicates individual resource turnover rates and tolerance of drought stress. The most important consideration in choosing which traits to measure is that they are indicators of functions relevant to the question FD indices are being used to answer. For example, to test if more functionally diverse plant communities have higher primary productivity, traits that indicate growth rates and complementarity in resource use should be measured (e.g., SLA for growth rate and leaf inclination for complementarity in light capture).

Criteria Required for Valid Functional Diversity Indices

The primary criterion for all FD measures is that they should be independent of existing biodiversity measures, such as species richness. If FD indices merely replicate the information provided by other measures, then they will do nothing to enhance our understanding of ecological processes. Several authors have suggested differing sets of criteria in addition to this for FD indices. However, given that indices intended to measure each FD component will necessarily have differing behavior, not all criteria will be applicable to all FD indices. Table 1 provides a list of criteria, with their applicability to each component of FD.

A Review of Existing Measures

A range of existing FD measures is reviewed, though this should not be considered an exhaustive list. Further reading is available in existing reviews of FD measures by Schleuter *et al.* (2010), Pavoine and Bonsall (2010), and Mouchet *et al.* (2010).

In reviewing existing measures, we group them according to each of the three FD components. This is not possible for all indices, because some are a combination of functional richness and functional divergence. There is also an assessment of the validity of each index against the criteria listed. Although the original definition of FD components by Mason *et al.* (2005) explicitly incorporates intraspecific variation in functional traits, few indices make an attempt to do so. Increasingly consideration is being given to the inclusion of intraspecific trait variability in deriving new FD indices (Cianciaruso *et al.*, 2009; De Bello *et al.*, 2010b; Schleuter *et al.*, 2010), and indices that do this are noted where they are available.

Functional Richness

Although this component contains perhaps the largest number of indices, they are based primarily on four major approaches. First of all is the functional group richness approach, where species are categorized either into *a priori*

Table 1 Criteria required for valid functional diversity indices. Yes and No indicate whether or not criteria are relevant for each functional diversity component

Criterion	Functional diversity component		
	Richness	Evenness	Divergence
1: Be constrained to a 0–1 range (for convenience) and use that range well	Yes	Yes	Yes
2: Reflect the range of character values present	Yes	No	No
3: Reflect the contribution of each species in proportion to its abundance	No	Yes	Yes
4: Decrease when the abundance of a species with an extreme trait value decreases	No	No	Yes
5: Be unaffected by the units in which traits are measured	Yes	Yes	Yes
7: Be unaffected by the units in which the abundance is measured	Yes	Yes	Yes
8: Be unaffected by the number of species	Yes	Yes	Yes
9: Be unaffected when a species is split in two (i.e., is replaced by two with the same character value, with the same total abundance)	Yes	Yes	Yes
10: Have set monotonicity (a set of species is as or more diverse than any subset drawn from it)	Yes	No	No
11: Have concavity (average diversity of local communities is less than the diversity of regional species pool)	Yes	No	No

groups, or groups defined by functional traits. Functional richness is measured as the number of functional groups present. Since this approach is dealt with at length in the “functional diversity” entry of this encyclopedia, it is not considered further here.

Second, there are a variety of dendrogram-based FD measures, the first of which was published by [Petchey and Gaston \(2002\)](#). These measures begin by building a matrix of pairwise distances between species in functional trait space. They then use hierarchical classification techniques to cluster species together based on these distances. Usually, a single dendrogram is built for all the species within a study area, or species pool. FD values for local communities (or other subsets of the species pool) are estimated as the total branch length required to link the species present in the community on the dendrogram ([Figure 2](#)). Taking this approach allows dendrogram FD measures to satisfy the set monotonicity and concavity criteria, since FD of local communities will always be lower than for the entire assemblage, and FD will increase monotonically with species richness. Dendrogram FD measures can be constrained to a 0–1 range if raw FD values for subsets of the species pool are expressed as a proportion of the total branch length of the dendrogram including all species in the pool. The dendrogram approach has recently been extended to include intraspecific variation, but the behavior of this approach has been little explored ([Cianciaruso et al., 2009](#)).

One of the problems with dendrogram-based measures is that distances between species on the dendrogram are often poorly correlated with species distances in functional trait space. This arises as dendrograms are an attempt to reduce the dimensionality of functional trait space to allow relationships between species to be visualized. This necessarily entails some distortion of species distances in functional trait space. One attempt to minimize this distortion has been to choose a dendrogram from a range of potential distance metric and clustering method combinations, including “consensus trees” (which build a composite dendrogram that retains only the nodes supported by the majority of the dendrograms considered; [Mouchet et al., 2008](#)). However, in most instances,

Figure 2 A simplified example illustrating how species distribution in two dimensional functional trait space is converted to a matrix of pairwise distances in trait space between species, which is then used to build a functional dendrogram. In a community containing only species A and B, functional richness is the summed length of the solid lines. The functional richness of the species pool is the sum of all branch lengths. Reproduced from Poos MS, Walker SC, and Jackson DA (2009) Functional-diversity indices can be driven by methodological choices and species richness. *Ecology* 90: 341–347, with permission from Wiley.

even the strongest correlation between distances in functional space and on dendrograms is relatively low ($r < 0.4$). This discrepancy between functional dendrograms and species distribution in functional trait space brings into question whether dendrogram measures are suitable as FD indices following the definition above. Another issue with dendrogram-based FD

measures is that they tend in practice to be very strongly correlated with species richness. The effect of species richness on dendrogram-based FD dominates variation in FD between communities, so that differences in FD between communities generally reveal nothing more than the fact that those communities differ in species richness (Poos *et al.*, 2009).

The third major approach to the estimation of functional richness is convex hull volume (CHV, Cornwell *et al.*, 2006). This approach defines the minimum volume of functional trait space required to include the species within a local community. For a single functional trait, CHV is simply the range of trait values (i.e., the FRI of Mason *et al.*, 2005), but when two or more traits are involved, a complex algorithm is required to define CHV. CHV conforms to the set monotonicity criterion, since the addition of new species will result in either no change, or an increase in hull volume. CHV also conforms to the concavity criterion, since the hull volume of the regional species pool will always be greater than or equal to that of any local community. CHV can be converted to a 0–1 range if values for local communities are divided by those for the entire species pool.

The convex hull approach tends to be less sensitive to species richness than dendrogram-based approaches (Mouchet *et al.*, 2010). However, one potential drawback is that CHV is undefined when the number of species is less than or equal to the number of traits. For example, in a two-dimensional functional trait space, at least three species are required to form a convex hull. This means that the number of dimensions in functional trait space must be less than the species richness of the least species-rich community. This can cause a tradeoff between the inclusion of more traits and the inclusion of species-poor communities. One solution to this problem has been to reduce the dimensionality of functional trait space using ordination techniques (Figure 3), such as principal components analysis (PCA) or principal coordinates analysis (PCoA). However, reducing the number of dimensions runs the risk of losing some of the information from the raw trait data.

The final approach (FRis and FRim) differs from dendrogram and convex hull based estimates of functional richness in that it incorporates intraspecific trait variability. This permits estimation of not only the volume of trait space occupied by species, but also how completely this occupied trait space is filled (Schleuter *et al.*, 2010). For one-dimensional trait space the index FRis uses intraspecific trait variability to find the union of the trait ranges of individual species (i.e., the combined range of functional trait values occupied by individual species, Figure 4). In multidimensional trait space, the index FRim uses intraspecific trait variability to define a membership probability function, which estimates the probability that a species “belongs to” a given point in trait space. The functional richness of the community is then computed as the integral of the maximum membership probability values across the species present in the local community (illustrated for a single trait in Figure 4). This index conforms to both the set monotonicity and the concavity criteria since the functional richness of the regional species pool will always be greater than or equal to that of local communities or other subsets of species. Both the single and multidimensional versions of this approach can be converted to a 0–1 range if

Figure 3 A simplified example illustrating the need for ordination to reduce dimensionality in functional trait space for the calculation of convex hull volume when the number of traits is greater than the number of species. In this example we have 10 traits and four species. The trait data are used to calculate pairwise distances between species using all 10 traits, then principal coordinates analysis (PCoA) is used to derive ordination axes from these distances. Reducing the dimensionality of functional trait space to the first two PCoA axes allows us to calculate convex hull volume for communities containing at least three species. The functional richness of a local community containing species A, B and D is the volume enclosed by the solid lines. The functional richness of the species pool is the volume contained in the lines connecting species A, B and C.

values for local communities are divided by those for the entire species pool.

The main advantage of these indices is that in considering not only the volume of functional trait space spanned by the species present, but also how much of that volume is occupied, they provide a closer representation of the functional richness concept as defined by Mason *et al.* (2005). However, because of the novelty of these indices, it remains unclear whether they are more strongly affected by species richness than ecological processes. Further tests of these indices following the methods of Mouchet *et al.* (2010) and Poos *et al.* (2009) will help to better assess the practical usefulness of these indices. One drawback of these indices is that there is a degree of arbitrariness in defining the volume of functional trait space occupied by individual species. Schleuter *et al.* (2010) use the 5th and 95th percentile of trait values to define this, though other options, such as the minimum and maximum trait measurements, would be possible. It remains

Figure 4 Functional richness measures incorporating intraspecific variation for either (a) single traits or (b) in multidimensional trait space (demonstrated using a single trait for simplicity). In (a), functional richness is the sum of the distances between the dotted lines, which indicate the range of trait space occupied by each species. In (b) the bell shaped curves indicate the membership probability (i.e., the probability that a species belongs to a particular point in functional trait space). The functional richness of the community in (b) is the integral of the maximum membership probability amongst the species present, which is represented by the gray shaded area.

unclear whether this choice may have an effect on the outcome of functional richness comparisons between communities. Another issue is that these indices are unable to deal with categorical trait data, since they require intraspecific trait variation.

Functional Evenness

Compared with functional richness, there are comparatively few indices of functional evenness. The two existing indices are single and multidimensional measures of “functional regularity” (FRO, Mouillot *et al.*, 2005a), which is an extension of the Bulla (1994) index for evenness in species abundance. The single-dimension version measures the evenness in distances between nearest-neighbor species, weighted by relative abundance (Figure 5). This equates to an abundance-weighted measure of how evenly spaced species are along a functional trait gradient. This index was extended to consider multidimensional trait space with the index FEve, by using a minimum spanning tree algorithm to calculate the distances between nearest-neighbor species by Villegger *et al.* (2008). The original FRO index was then used to calculate the abundance-weighted regularity in these distances.

It should be noted that the concept of functional evenness is not *a priori* dependent on the regularity of species spacing in functional trait space. Rather it is solely dependent on how evenly abundance is distributed in trait space. However, there are no indices available that quantify this directly. Consequently, FRO and FEve represent indirect estimates of

Figure 5 Illustration of communities with comparatively high and low values for the functional evenness estimator FRO (A) and its multivariate extension FEve (B). In the high FRO example, the perfect evenness in abundance and perfect regularity in spacing between nearest neighbor species along the trait gradient would give an FRO of 1. In the low FRO example, the variation in distances between nearest neighbors would cause a decrease in FRO. In the two FEve examples, species abundances are proportional to the diameter of the circles. In the high FEve example, the perfectly even abundances and the identical distances between nearest neighbor species in two dimensional trait space (as defined by the minimum spanning tree) would yield an FEve value of 1. The low FEve example would yield a decreased value due to the variability in nearest neighbor distances.

functional evenness. Nevertheless, both these indices conform to all the criteria relevant to an index of functional evenness, except that when a species is split into two functionally identical species with the same total abundance, FRO decreases. This will mainly be a problem when communities contain a large number of cryptic species (i.e., morphologically similar species that are difficult to separate in the field). Where there is a high level of confidence in species identification it will not be an issue. For the moment, the lack of an alternative approach to functional evenness measurement means that this is the best option available.

Functional Divergence

Since the original definition of functional divergence by Mason *et al.* (2005), there has been some confusion about how to measure it. Initially, Mason *et al.* (2005) proposed FDvar (see Indices Combining Functional Richness and Functional Divergence) as a measure of functional divergence. However, FDvar is affected by the range of functional trait values, so it is dependent on functional richness. As noted (see Defining Functional Diversity), the intention of dividing FD into three components was to separate it into independent, measureable concepts, so it is undesirable for indices measuring one component to be affected by another. Since then, several other measures have been presented, which are in effect a combination of functional richness and functional divergence, and these are reviewed below (see Indices Combining Functional Richness and Functional Divergence).

Figure 6 Illustration of the multivariate FDiv index for estimating functional divergence. The solid lines indicate the convex hull containing all the species present and the species connected by the solid line are the vertices of the convex hull. The diameter of the solid circles is proportional to species abundance. The open circle is the unweighted centre of gravity (i.e., group centroid) of the species forming the vertices of the convex hull. The dotted circle is the unweighted mean (taken across all species) of the species distances from the centre of gravity. In the example with a high FDiv value, distance of the most abundant species from the centre of gravity is greater than the mean distance. In the low FDiv example, the distance of the most abundant species from the centre of gravity is less than the average distance.

The only pure indices of functional divergence are the FDiv of [Villegier et al. \(2008\)](#) and the FDs of [Schleuter et al. \(2010\)](#).

FDiv measures the degree to which the abundance of a community is distributed toward the extremities of occupied functional trait space. It does this by first finding the convex hull for the species present (see [Figure 3](#)). It then finds the coordinates of the center of gravity for the convex hull by calculating the nonweighted mean across the species forming the vertices of the convex hull (i.e., the group centroid of the species forming the convex hull, [Figure 6](#)). Finally, it applies a series of equations to compare the observed sum of abundance-weighted Euclidean distances of species from the center of gravity relative to the maximum possible value. FDiv conforms to all the relevant criteria for a measure of functional divergence. The major drawback of FDiv is that it depends on the construction of a convex hull around the species in functional trait space. As noted above (see Functional Richness), this may constrain either the maximum number of functional traits or the minimum species richness allowable for calculation of FDiv, since the construction of a convex hull requires species richness to be greater than the number of trait dimensions. However, FDiv remains the only available multi-dimensional measure of functional divergence.

FDs is the abundance-weighted interquartile range of trait values, divided by the total range of trait values. In the original presentation [Schleuter et al. \(2010\)](#) provide for abundance weighting in finding the first and third quartile trait values by assuming species abundances are measured on a discrete scale (i.e., as counts of individuals). In this case, the quartile values are found simply by replicating species mean trait values in accordance with the number of individuals counted for each species. Obviously there are many instances where measurement of species abundance using counts of individuals is neither possible, nor desirable. In these cases, it will still be possible to calculate FDs since continuous abundance

measurements may be used to weight quartile values as well. FDs conforms to all the criteria relevant for a measure of functional divergence. Its only limitation is that no multi-dimensional analog has been found.

Indices Combining Functional Richness and Functional Divergence

In recent years several indices have been developed, which incorporate both functional richness and divergence, since they are affected both by the range of functional trait space occupied and the degree to which the abundance of a community is distributed toward the extremities of this occupied space. Most of these indices are variants on the theme of abundance-weighted deviance of species trait values from the weighted community mean trait value. The other approach is Rao's quadratic entropy, which was applied as a FD measure by [Botta-Dukat \(2005\)](#).

The first index quantifying the abundance-weighted squared deviance of trait values across species was the FDvar of [Mason et al. \(2003\)](#). This index first calculates the abundance-weighted mean of log-transformed functional trait values across species (log-transformed values are used to ensure the index is independent of the units in which trait values are expressed). It then calculates the abundance-weighted sum of squared deviances of species log-transformed trait data from this weighted mean. Finally, the arc tangent of the resulting sum of squares is taken to ensure the index is bound between 0 and 1. FDvar conforms to all the relevant criteria for an index of functional divergence, except that it is sensitive to the range of functional trait values ([Figure 7](#)). FDvar does not conform to the set monotonicity and concavity criteria for an index of functional richness. Apart from this, the main practical drawback of FDvar is that it cannot deal with trait values of 0 (except by adding an arbitrary amount), since the log of 0 is undefined. [Leps et al. \(2006\)](#) proposed a modified version of FDvar, which does not log transform trait values or use the arc tangent of the abundance-weighted squared deviance in trait values to constrain the index between 0 and 1. This obviously has the drawbacks that index values may be affected by the units in which traits are measured and observed values of the index are not readily interpretable, since it is not bound between 0 and 1. The problem of comparing index values between traits measured in different units can be circumvented by standardizing trait values so they have a mean of 0 and variance of 1, or by expressing trait values relative to the range of observed values.

[Laliberte and Legendre \(2010\)](#) presented a multivariate extension of the [Leps et al. \(2006\)](#) modification of FDvar, which they termed functional dispersion. This is essentially the abundance-weighted sum of deviances in multivariate trait space taken across species. The functional dispersion index first finds the abundance-weighted group centroid by calculating the abundance-weighted mean for each trait. It then sums the abundance-weighted deviance from this centroid across species. This index conforms to all the criteria relevant for measures of functional divergence, except that it is not bound between 0 and 1 (though this is only important for ease of interpretation of observed values). It does not conform to the set monotonicity criterion and no mathematical proof

Figure 7 Illustration of the dependence of FD_{var} on both functional richness and functional divergence. Comparison of panel A with panel B demonstrates that FD_{var} increases when the most abundant species have extreme trait values (a feature of functional divergence). Comparison of panels A and C shows that FD_{var} also increases as the range of trait space occupied increases (a feature of functional richness). The same applies to adaptation of FD_{var} proposed by Leps *et al.* (2006) and to the index of multivariate dispersion presented by Laliberté and Legendre (2010), which is essentially a multivariate extension of the index presented by Leps *et al.*

has been provided to show that it conforms to the concavity criterion. In practice, functional dispersion appears to be very strongly correlated with quadratic entropy.

Rao's quadratic entropy is the sum of abundance-weighted pairwise distances between species in functional trait space. Since this index is sensitive both to the volume of functional trait space occupied and the degree to which abundance is distributed toward the extremities of this occupied trait space, it incorporates both functional richness and functional divergence (Figure 8). It does not conform to the set monotonicity criterion but does have concavity if regional abundances are calculated appropriately (Ricotta, 2005). This index also conforms to all the criteria relevant for a measure of functional divergence, except that it is not always bound between 0 and 1 (although using distance metrics such as Gower's distance Rao will be bound between 0 and 1, it will not necessarily use the entire range of values within these bounds). Other than this, quadratic entropy does not have any obvious drawbacks.

Recommendations

CHV and FR_{im} are emerging as the most promising measures of functional richness. Their strength is that they are tightly linked to species distribution in functional trait space, whereas dendrogram measures of functional richness are a distortion

Figure 8 Illustration in two dimensional functional trait space of the dependence of Rao's quadratic entropy (Rao) on both functional richness and functional divergence. Rao is the sum of the abundance-weighted pairwise distances between species in functional trait space (the solid lines connecting the filled circles). The diameter of the filled circles is proportional to species abundance. Comparison of A with B shows that Rao increases when the most abundant species occur at the extremities of occupied functional trait space (a feature of functional divergence). Comparison of A with C shows that Rao also increases as the volume of trait space occupied increases (a feature of functional richness).

of this distribution. FR_{im} has the advantage that it does not require species richness to be greater than the number of functional traits, so ordination techniques are not required to reduce the dimensionality of functional trait space. It also has the advantage of measuring how completely species fill the volume of trait space occupied, and so provides a closer representation of the functional richness concept. Because both indices are relatively new, simulation and field studies are required to determine whether one or the other has greater power to reveal ecological processes. For functional evenness, choices are limited to FRO and its multidimensional analog FEve. Its failure to satisfy all criteria is nontrivial, and its use should be restricted to situations where species identifications can be made with a high degree of certainty. Despite this, FRO has proven useful in revealing ecological patterns (Mason *et al.*, 2008). For functional divergence, FDiv provides a useful multivariate measure, and its ability to reveal ecological processes has recently been demonstrated (Mouillot *et al.*, 2011). FDs has yet to be applied to real ecological questions, so its practical usefulness remains unclear, although it is mathematically sound. Among the composite measures of functional richness and functional divergence, Rao quadratic entropy is the most suitable because it satisfies most of the important criteria for both types of index. In particular, the fact that it conforms to the concavity criterion opens up interesting possibilities for exploring ecological questions.

Application of FD Measures to Answer Ecological Questions

FD measures have a dual role as potential indicators of ecosystem functioning, such as primary productivity, and of the processes that govern the assembly of species into communities, since complementarity between species in resource use and acquisition may both increase rates of ecosystem function and facilitate coexistence between species. In addition to this, indices that conform to the concavity criterion open up the possibility that hierarchical partitioning of FD measures may be used to estimate FD at local (α), regional (γ), and beta scales. Below we provide an example demonstrating the link between FD measures and ecosystem function in experimental grassland communities and an example showing how FD measures can reveal community assembly processes in lacustrine fish communities. Finally, we provide an example of how hierarchical partitioning can reveal changes in FD at multiple scales along a gradient of declining soil phosphorous. Because development of continuous FD measures has been so rapid in recent years, there are only a limited number of examples of their application to answering ecological questions relative to the number of indices available. We anticipate a wide variety of innovative applications of FD measures in the future. Consequently, these examples are not intended to provide a guide for the application of FD measures, but to highlight some of their potential applications.

Example 1: Ecosystem Function in Experimental Grassland Communities

The niche complementarity hypothesis states that differences between species in their functional traits will enhance

ecosystem functioning by allowing greater complementarity in resource use between species, which will in turn increase the total amount of resources available to the community. In plant communities, niche complementarity predicts that primary productivity rates should be enhanced by increasing FD. Enhanced primary productivity, by increasing the energy and nutrients available to consumers, is likely to increase consumer diversity, which may increase rates of function (especially litter decomposition) in consumer communities. Mouillot *et al.* (2011) tested these ideas by comparing the relative influence of species richness, evenness in species abundance, functional identity (community trait means weighted by relative abundance), and FD measures on a measure of ecosystem multifunctionality at an experimental grassland near Bayreuth, Germany. This site was part of the pan-European project BIO-Diversity and Ecological Processes in Terrestrial Herbaceous ecosystems (BIODEPTH), where communities differing in plant diversity were established from seed.

Ecosystem multifunctionality was calculated as the mean performance of communities over four processes (above-ground biomass production, litter and cotton decomposition, and assimilation of nitrogen in live aboveground vegetation) after standardizing each community process (mean of 0 and standard deviation of 1) in order to give them the same weight. The FD measures used were CHV for functional richness, FEve for functional evenness, and FDiv for functional divergence, all of which are described in Villegger *et al.* (2008). Six functional traits were measured in total, containing a mixture of continuous and categorical variables. To allow the inclusion of the categorical variables in FD calculations, PCoA was performed. This resulted in three independent functional trait axes. The distribution of species in functional trait space was thus described by species positions along each of these axes. For each community, FD was calculated using PCoA coordinates instead of raw functional trait measurements with species aboveground biomass as the measure of abundance. Analyses were restricted to communities with four or more species since CHV and FDiv may only be calculated when species richness is greater than the number of dimensions in functional trait space. Community weighted mean (CWM) values were calculated as the abundance-weighted mean coordinate value for each PCoA axis. Species richness was fixed at the number of species sown in the original community, whereas evenness in species aboveground biomass was estimated using the Pielou index.

These eight indices of community structure were used as predictor variables in a structural equation model (SEM) to predict ecosystem multifunctionality. The SEM showed that FDiv had a strong positive effect on multifunctionality, independent of the other community structure variables (Figure 9). It also showed that CWM values for PCoA axis 1 had a positive and those for PCoA axis 3 a negative relationship with multifunctionality. Overall, the SEM revealed a synergistic effect of FDiv and functional identity (CWM values) on ecosystem function, indicating that highest rates of function were achieved by communities that had particular CWM values and where the most abundant species were complementary in their functional traits. This example shows how SEMs, in combination with field experimental data, can reveal the impact of FD on ecosystem function. Multiple

Figure 9 Relationship between ecosystem multifunctionality and functional divergence (as estimated by FDiv). Multifunctionality was estimated as the mean of standardised values taken across four measures of ecosystem function (above-ground biomass production, litter and cotton decomposition and assimilation of nitrogen in live above-ground vegetation). This explains why some of the plots have negative values for multifunctionality.

regression analyses show that FDiv had a strongly significant positive effect on all four of the ecosystem processes examined, suggesting that increased functional divergence in plant communities can enhance not only primary productivity but also rates of decomposition and nutrient cycling within grassland ecosystems.

One complication of this example is that the PCoA axes are not immediately functionally interpretable. Subsequent analyses show that the effect of FDiv was largely due to differentiation along PCoA axes 1 and 3. Axis 1 is largely a contrast between plants with vertical leaves and plants with horizontal or inclined leaves. Axis 3 is a contrast between plants with evergreen and nonevergreen leaves. Thus, the results of Mouillot *et al.* (2011) suggest that ecosystem function is enhanced by complementarity in resource use between species differing in leaf inclination and phenology. Differences in leaf inclination allow complementarity in light capture between species, which can enhance the total amount of light absorbed in photosynthesis for the community as a whole, whereas differences in phenology allow temporal differentiation in resource use between species, which enhances annual above-ground biomass and litter production. This enhancing effect of FDiv on productivity may be responsible for its relationship to decomposition rates, by increasing the flux of nutrients available to decomposer communities. Thus, although the use of ordination to reduce the dimensionality of trait space introduces some complexity in interpreting FD–ecosystem function relationships ecologically, it is still possible to find an ecological basis for the observed patterns.

Example 2: Assembly Processes in Lacustrine Fish Communities

Mason *et al.* (2008) used FD measures to explore mechanisms explaining species richness–energy relationships in French lacustrine fish communities. The study included 116 lakes covering most of France and including the island of Corsica. The lakes were divided among 11 major drainage basins,

spanning an altitudinal range from 4 to 2600 m (a.s.l.) and ranging in area from 1.4 to 5299 ha. The species composition dataset consisted of a matrix of species presence or absence within each lake. Sixteen functional traits were measured on up to 10 individuals for each species. They indicate three major aspects of resource acquisition/resource type in fish species – (1) mode of food acquisition, (2) position in the water column or swimming behavior, and (3) preferred food type (Dumay *et al.*, 2004), thus providing information on aspects of the species niche that are relevant for coexistence in the local community. Functional richness was calculated using the FRI of Mason *et al.* (2005, which is the same as CHV for a single trait) functional evenness was estimated using the FRO index of Mouillot *et al.* (2005a), whereas niche overlap was also calculated following the method of Mouillot *et al.* (2005b). FD and niche overlap values were calculated for each trait separately, with the mean value then being taken across traits. Values were expressed relative to those expected when species occurrences were randomized to ensure that the observed relationships were not simply due to chance.

The first test was whether the FD indices had a linear or saturating nonlinear relationship with species richness. Next the effect of mean air temperature, lake surface area, maximum water depth, surface area of the upstream drainage basin, regional species richness, and FD of the regional species pool on species richness, FD, and niche overlap was assessed using multiple regression. The intention was to test whether energy (temperature), habitat diversity (lake area and water depth), and immigration potential (catchment size and regional species richness and FD) had a dominant effect on local FD, niche overlap, and species richness.

The quadratic model provided the greatest amount of explanatory power for the relationship between functional richness and species richness. This indicates that the ratio of observed to expected functional richness (i.e., volume of niche space occupied) either peaked or saturated at moderate levels of species richness (Figure 10). The power function had the greatest explanatory power for niche overlap, yielding a relationship where overlap decreased sharply initially with increasing species richness, and then showed only a slight decrease with subsequent increases in species richness (Figure 10). There was strong evidence for a linear relationship between functional evenness and species richness with only slight signs of saturation until the very highest levels of species richness (Figure 10). These results indicate that although the volume of trait space occupied did not increase at the highest levels of species richness, an increase in overlap was avoided because species became more evenly spaced within the occupied trait space. This in turn suggests that increased niche specialization facilitated species coexistence at the highest levels of species richness.

Mean air temperature was the variable with the greatest explanatory power, for species richness, all measures of FD, and niche overlap in multiple regression (Figure 11). The effects of all other explanatory variables were minor in comparison. There was some evidence for a nonlinear relationship between species richness and mean annual temperature, though there was not enough evidence to reject the linear model (Figure 11). The linear model received the greatest support for the functional evenness–temperature relationship.

Figure 10 Relationships between functional diversity, niche overlap and species richness in French lacustrine fish communities. Functional richness was measured using the FRi of Mason *et al.* (2005) while functional evenness was estimated using the FRO of Mouillot *et al.* (2005). Functional diversity and niche overlap values are expressed relative to those expected when species co-occurrences are randomised.

These results, combined with the relationships between functional evenness, niche overlap, and species richness, suggest that increased energy inputs may permit species coexistence in the most species-rich communities by allowing species with specialized niches to maintain viable populations.

Low-energy lakes are dominated by generalist carnivores that may feed efficiently on other fish and insects at all positions in the water column (e.g., trout – *Salmo trutta* – and other salmonid species). High-energy lakes include specialist piscivores (e.g., the pikeperch *Sander lucioperca* and Wels catfish, *Silurus glanis*), specialist benthic feeders (e.g., the bream, *Abramis brama*), and species with strong herbivorous tendencies (e.g., the common carp). Primary productivity and zooplankton density increase with temperature in lake ecosystems. However, it is uncertain whether increasing temperature causes an increase in the availability of resources

used by specialists. Evidence for the “niche specialization” hypothesis would be provided by finding that the density of resources used by specialists (e.g., fish prey species, benthic invertebrates, or detritus and macrophytes) increases with increasing temperature. This evidence would be strengthened by a positive relationship between the probability of occurrence or population density of niche breadth specialists within lakes and the density of the resources, which they are specialized to exploit. Full confirmation would require demonstration that increased density of these resources was associated with a decrease in the probability of local extinction (or periods of low population density) for specialist species. Thus the example of Mason *et al.* (2008) demonstrates that although FD measures may reveal patterns that are suggestive of community assembly processes, additional work is generally required to confirm the link between observed patterns and inferred processes.

Example 3: Hierarchical Partitioning of FD along a soil Phosphorous Gradient

Mason *et al.* (2011) examined changes in FD at local, regional, and beta scales along a soil phosphorous gradient associated with a soil chronosequence generated by a retreating glacier in a super-humid region of New Zealand. The intention was to test whether the relative influence two contrasting assembly processes (environmental filtering and niche complementarity, Mason *et al.*, 2011) varied as soil P declined at any of these scales. Theoretically, the influence of environmental filtering on community assembly should increase as nutrient stress intensifies, so that FD should decrease with declining soil P. Four traits (leaf N and P, leaf thickness, and density) that indicate species resource use strategy (i.e., fast and leaky resource acquirers versus slow and tight resource retainers) were measured for the woody species occurring at each of eight sites along the chronosequence. Diameter measurements were used to estimate species basal area within three circular plots of 10 m radius at each site. Local (alpha) FD was calculated as the mean of Rao’s quadratic entropy (taken across plots within each site), using basal area as the abundance weighting. Regional diversity was calculated at the site scale, with Rao values calculated using species mean proportional abundance taken across the three plots as an abundance weight. Beta FD was estimated by subtracting local Rao from the corresponding regional value. All calculations followed the methods of De Bello *et al.* (2010a). In addition to examining patterns for raw Rao values, Mason *et al.* (2011) compared observed local Rao values with those expected when species abundances were randomly allocated within communities. This method has proven very powerful in revealing evidence for community assembly processes in plant, fish, and plankton communities. Here, higher Rao than expected provides evidence for niche complementarity, whereas lower Rao than expected provides evidence for environmental filtering.

There was no evidence of a decline in raw local Rao values when weighting by basal area (Figure 12). However, there was a strongly significant decline in local Rao values expressed relative to random expectation (Figure 12). This result suggests that constraints on the functional traits required to

Figure 11 Relationships between functional diversity, niche overlap and mean annual temperature in French lacustrine fish communities.

Figure 12 Observed Alpha Rao quadratic entropy and Alpha Rao relative to random expectation (Alpha Rao Monte Carlo) for each site along the chronosequence versus total soil P. Each point represents a single site along the chronosequence. OLS R^2 is R-squared from ordinary least squares regression. Other statistics are from Jack-knifed linear regression.

Figure 13 Regional (site) and beta (between plots but within sites) Rao quadratic entropy for each site along the chronosequence versus total soil P. Each point represents a single site along the chronosequence. OLS R^2 is R-squared from ordinary least squares regression. Other statistics are from Jack-Knifed linear regression.

achieve high abundance became much more severe as soil P declined. There was no relationship between regional (site) Rao and total soil P, but Beta Rao was significantly negatively correlated with total soil P (Figure 13). This indicates that

communities became functionally more homogeneous as nutrient stress increased.

The fact that a decline in local FD with declining soil P was only observed when raw Rao values were compared with

random expectation indicates that the ability of FD indices to reveal evidence for ecological processes may be highly dependent on how they are expressed. The decline in beta diversity suggests that the functional composition of local communities became much more deterministic with declining fertility, indicating that the limitation imposed by abiotic stress on local FD also increased homogeneity in functional composition across local communities. This example shows that the comparison of raw FD values with random expectation and the hierarchical partitioning of FD provide two potentially powerful methods for the application of FD indices in revealing community assembly processes.

Glossary

Environmental variables Abiotic and biotic elements of an area including vegetation, soil, topography, species competition, geology, prevalence of diseases and hydrologic characteristics, among others. Habitat selection can be positively or negatively related to these environmental variables.

Habitat An area where an organism resides is comprised of abiotic and biotic elements.

Habitat patch A spatially contiguous area in which environmental variables are similar.

Habitat selection The act of choosing the combination of available abiotic and biotic elements for the purpose of fulfilling the life history events of the organism.

Hierarchical habitat selection This concept recognizes that an organism's selection of habitat occurs at varying spatial and temporal scales. The scale at which different selections occur are ordered; First-order (habitat selections defining the species range), Second-order (selections defining the placement of an individual's home range within the species range), Third-order (within home range selections), and Fourth-order (fine-scale daily habitat selections).

Introduction

Habitat is a theoretical construct used to describe the living space of an organism. As such, habitat includes the suite of interacting abiotic (e.g., weather, soils, topography, and hydrology) and biotic (e.g., vegetation structure and composition, inter- and intraspecific competitions, and prevalence of diseases) elements that influence whether an organism uses a particular location. Habitat selection is the act of choosing the combination of available abiotic and biotic elements for the purpose of fulfilling the life history events of the organism (e.g., mating, raising young, and avoiding death). An organism's selection of habitat varies across space and time as certain needs are fulfilled and others pursued. The objective of habitat selection research is to describe why organisms use various combinations of environmental (abiotic and biotic) variables, an understanding of which informs population or species conservation. The concept of habitat selection can be extended to plants and fungi but animals are the most common research subject.

When discussing the concept of habitat selection it is important to differentiate among habitat use, habitat selection, and habitat preference because each concept has important management and conservation implications. Habitat use refers to organisms occurring in an area, not necessarily by choice. Habitat selection implies that an organism made a choice about occurring in a particular location, that is, the organism had multiple options and for some reason (presumably to efficiently satisfy a life history event) chose to occur at a particular location. Habitat preference is applied at the species-level and refers to the habitat that the species prefers above all others, even if that habitat is unavailable in the landscape where a local population resides. Habitat preference is the most difficult concept to quantify because in most areas organisms are not free to choose among an unrestricted set of environmental variables. Thus, researchers tend to focus their efforts on quantifying habitat selection and use. Knowledge of preferred habitat may elude researchers because of the

inability to comprehend the exact combination of environmental variables that would be selected if all were available. This reality has conservation implications which could potentially compromise organism, population, or even the species persistence into the future.

The origin of habitat selection research is based on the observation of animals by naturalists. One of the earliest documented naturalists was Aristotle who took a keen interest in animal-habitat associations (Morrison *et al.*, 2006). Since Aristotle, both informally and formally trained naturalists and ecologists have studied how organisms use their environment. This was certainly of concern to nineteenth century naturalists who examined the morphology and relatedness of certain species as the basis for concepts like biogeography and speciation (Wallace, 1876). These naturalists realized that the selection of habitat had important evolutionary ramifications (Darwin, 1859). The interaction of an organism with habitat was later framed as the ecologic niche (Grinnell, 1917). Niche theory developed into a research area unto itself with ecologists being principally concerned with how organism-habitat interactions shape fitness (Petren, 2001).

The twentieth century saw an expansion in research methodologies used to study habitat selection. The collective goal of these methodologies was to identify the location of organisms across spatial and temporal dimensions and to examine the environmental variables associated with those locations. Habitat selection research broadly consists of two phases: (1) Documenting habitat used by an organism of interest and (2) making inferences on why habitat was selected (usually based on a comparison of habitat use and availability). The first step in quantifying habitat use is to map organism locations. Multiple techniques are used to locate organisms in space including direct visual observation, conducting visual or auditory surveys, using traps or other evidence of occurrence (i.e., scat, tracks, and carcasses), and telemetry technology (Figure 1). Each of these techniques results in animal location(s) that can be related to a suite of environmental variables which collectively define habitat.

Figure 1 Four techniques used to locate organisms in environmental space, (a) direct visual observation, (b) visual surveys, (c) trapping (camera trapping), and (d) telemetry.

Once animals are located and the environmental variables of interest are measured, habitat selection can be quantified.

Measurement of Animal Locations

Direct Visual Observation

Directly observing animals in their habitat is the oldest technique used to measure habitat selection. This process involves researchers following single or multiple animals through environmental space while making notations about the environmental variables that are used to satisfy various life history events (Figure 1a). Though visual observation might appear to be a relatively simplistic means of evaluating habitat use, increasingly complex methods of sampling have been employed in animal behavior research (Altmann, 1974). *Ad-libitum* sampling, focal animal sampling, and all occurrence sampling are common direct visual observation techniques used to assign the location of an organism with the environmental variables that describe habitat.

Ad-libitum sampling is a form of visual observation where the researcher documents habitat use in an *ad-lib*, or opportunistic fashion. As such, *ad-libitum* sampling most aptly describes the technique used by early naturalists. A field notebook is commonly used to record environmental

variables chosen by the organism of interest. This sampling scheme is notoriously difficult to quantify with reliability because of the opportunistic fashion in which the data are recorded. Thus this technique has been criticized for being more anecdotal than empirical (Altmann, 1974; Mann, 1999). However, *ad-libitum* sampling can be useful in pilot studies or in situations where a researcher is attempting to document the variety of environmental variables used by an organism over limited spatial and temporal dimensions (Altmann, 1974).

Focal animal sampling involves the detailed observation of a single organism at specified intervals over a period of time. For instance, a researcher would identify an individual to observe and would follow that individual wherever it goes recording all behaviors, including environmental variables that are used. The researcher notes the type of behavior, the duration of the performed behavior, whether or not the behavior involved interactions with other individuals or organisms, and any other environmental variables that were used. This type of sampling would continue for a specified interval (e.g., 5 min, 15 min, 1 h) at which point the researcher would break from recording data.

With all occurrence sampling, the researcher focuses on a specific behavior (such as selection of an environmental variable) and records any time that the behavior is performed throughout the sampling interval. This technique is widely employed in animal behavior research because it provides an

estimate of occurrence rate for a particular behavior. With this sampling technique the researcher can estimate how often a particular food item is selected, for instance, or how often cover habitat is selected per unit of time. All occurrence sampling can be useful in determining the relative dependence that an organism has for a particular environmental variable.

Visual and Auditory Surveys

Another set of research methodologies developed to identify the location of organisms in space at a particular time involves visual or auditory surveys (Figure 1b). Visual or auditory detection have been used to estimate species richness, produce population estimates, and characterize habitat selection. Several different methodologies exist but these can be categorized into two broad types; visual encounter surveys and auditory surveys.

Visual encounter surveys are widely utilized in ground, air, and ship-board capacities. In these cases the researcher scans the environment to visually identify individuals of the focal species. Various methods are used to conduct these surveys including line transects, randomized walk designs, and patch-based searches. Line transect surveys involve the designation of routes that researchers follow while searching for organisms (e.g., Otto and Roloff, 2011). Typically, the researcher limits the sampling to an area where organisms can be reliably detected. In random walk surveys the researcher follows a random path, while searching for organisms, for a specified distance (e.g., Gregory *et al.*, 2006). On reaching that distance, another random path is selected and followed after which the process is repeated. The advantage of this technique is that it can be an effective method for searching large areas, if the focal organism can be reliably observed. Patch-based surveys involve sampling all environmental variables within a given area. For example, if the goal of a survey is to identify birthing sites and the abundance and distribution of Hawaiian monk seals (*Monachus schauinslandi*) patch-based surveys would sample all beaches in the Hawaiian archipelago searching for females and their young during and directly after the pupping season (Baker and Johanos, 2004).

To conduct an auditory survey the researcher relies on sounds to identify and locate different organisms or species. Auditory surveys are particularly useful for vocal organisms like some birds and amphibians and include point counts and calling surveys. When employing point count surveys a number of locations or stations are identified where the researcher remains stationary listening for calls (e.g., Ralph *et al.*, 1993; Seavy *et al.*, 2009). The researcher stays on station for a specific period of time, documenting species occurrence through auditory and in some cases visual detection. The stations are typically spread across several different environmental variables that are relevant to the species of interest. Calling surveys involve surveyors searching certain areas with the goal of detecting where different organisms reside. These surveys are predicated on the idea that there are spatial and temporal conditions where certain species vocalize. Frogs and toads are common subjects of calling surveys (Pellet and Schmidt, 2005). The result of these surveys is the identification of environmental variables used by organisms of one

or multiple species. These surveys are designed to detect organisms, assign organism locations, and associate organism locations to specific environmental variables.

Trapping and Other Evidence of Occurrence

Another technique used to measure animal locations in the environment involves trapping (Figure 1c). There are a wide variety of trapping methodologies that include, but are certainly not limited to, baited traps (e.g., Cypher *et al.*, 2009), drift fences (e.g., Otto and Roloff, 2011), and pitfall traps (e.g., Müller and Brandl, 2009) that restrain animals so their presence, abundance, and location can be documented. Trapping can also be done in noninvasive fashions through the collection of images (photographs or video; e.g., Soisalo and Cavalcanti, 2006; Thorn *et al.*, 2009) or deoxyribonucleic acid (DNA) (hair snares; e.g., Gardner *et al.*, 2010). Trapping designs can include a grid, transect, or web network of traps, with traps spaced accordingly to increase the probability of detecting organisms (i.e., spacing based on home range size or known movement patterns). Like direct visual observation and visual or auditory surveys, trapping techniques can be used to associate organism locations with environmental variables on the landscape.

There are some concerns with trapping. With baited traps, in particular, it is possible that certain organisms will become conditioned to and potentially attracted to the trap. Within this context, study results would be biased if the researcher is repeatedly capturing the same individual or a cohort of individuals that are vulnerable to trapping. Conversely, if organisms associate a negative experience with being trapped, they may purposefully avoid traps and similarly bias study results. Furthermore, if multiple species are captured in the same trap it is possible to have competition and predation events where the presence of one species is being masked because it is consumed by another species. For example, it is well known that some species, such as shrews (family *Soricidae*) and opossums (family *Didelphidae*), will prey on other animals and insects captured in the same trap (Jurzenski and Hoback, 2011).

Researchers are increasingly using noninvasive techniques such as motion-activated cameras to photographically capture organisms or hair snares to collect DNA samples (Cutler and Swann, 1999; Gardner *et al.*, 2009; Figure 1c). The design of camera traps is quite similar to the aforementioned trapping procedures. Cameras are placed in a variety of environmental variables throughout the study area with the intention of documenting species occurrence or to produce population abundance estimates using mark-recapture on individuals. Individual identification of organisms is possible through visual acuity or with computer software programs which assist in the recognition of pelage patterns, markings, and other morphological characteristics specific to individuals. These methods effectively eliminate the necessity of restraining organisms and have the benefit of noninvasively documenting organism-habitat associations, although baited camera and hair snare traps are subject to the same biases described in the preceding paragraph for other baited trapping approaches.

Several additional techniques can be used to identify the position of organisms in space. These include locations where

evidence of organism presence persists including scat, tracks, and carcasses, among others. In these cases researchers are generally interested in describing specific life history events and collect data to describe those events. For instance, a researcher may be interested in quantifying the environmental variables that are characteristic of areas where organisms are subject to predation. All areas in the study can be searched in opportunistic or structured fashions to identify predator-killed carcasses (Kauffman *et al.*, 2007; Bump *et al.*, 2009). Once located, carcass sites can be associated with different environmental variables to determine the abiotic and biotic elements that correlate with predation events.

Increasingly complex forms of collecting organism locations are continually employed in habitat selection research. Remote sensing, satellite imagery, and infrared technology are now being used to study habitat selection in new and interesting ways. For instance, to document the distribution and abundance of harbor seals (*Phoca vitulina*) researchers are using aircraft fit with infrared technology to locate heat signatures of seals on ice flows (London and Richmond, 2010). This technology enables researchers to cover vast areas with increased reliability in the estimates of organism–habitat associations. Radar technology, typically used for describing the weather, is now being used to map concentrations of migratory birds (Bonter *et al.*, 2008). Large concentrations of birds at stopover sites along migratory pathways are viewed as selection for the environmental variables that coincide with these aggregations.

Telemetry

Telemetry technology has enabled increasingly complex spatial and temporal assessments of habitat selection. Telemetry, which literally translates to ‘remote measurement,’ was utilized by the U.S. Government to detect Cold War conflict and was retrofitted for animal research in the middle of the twentieth century (Benson, 2010). In 1960 Dwain Warner and John Tester were field testing Very High Frequency (VHF) radio tags on ruffed grouse (*Bonasa umbellus*). At about the same time John and Frank Craighead started fitting radio collars on grizzly bears (*Ursus horribilis*) in the Greater Yellowstone Ecosystem, a feat which earned notoriety through National Geographic coverage and a CBS documentary (Benson, 2010). The Craighead’s research led to publications in major peer-reviewed journals and a 1979 book titled *Track of the Grizzly*. The depth of this research and the notoriety that it garnered propelled telemetry technology to the forefront of habitat selection research. As a result, telemetry has developed into one of the main techniques used to study habitat selection.

Both VHF and Global Positioning System (GPS) telemetry depend on fitting an organism with a tag that transmits a signal and relocating that tag across space and time. For VHF telemetry data organisms are located through triangulating the radio signal (Mech, 1983). Tower-mounted, vehicle-mounted, or hand-held receivers are used to detect the tag signal and once detected a 3-dimensional fix is sought to improve precision in the location. Collecting VHF telemetry locations can be time consuming and logistically challenging. GPS technology has largely alleviated the time-intensive procedures

associated with VHF by allowing for more frequent locations (provided that a fix can be acquired) and automated or remote data download. With GPS technology, the radio tag communicates with satellites at preset intervals. Like VHF, at least a three-dimensional fix is required for GPS to precisely locate the radio tag. Regardless of the telemetry system used, the goal is to accurately locate the organism in space and connect the location to the environmental variables that describe habitat.

The main advantages of telemetry technology are the opportunities to seemingly study animal behavior in a non-invasive fashion. The close observation of organisms, characteristic of direct visual observation and some visual and auditory survey methodologies, has been scrutinized for the potential influence of the researcher’s presence on natural behavior (see Strum and Fedigan, 2000 for review). Similarly, potential bias associated with trapping can limit inference on habitat selection. In theory, telemetry technology permits collection of data via remote radio towers or portable telemetry units that minimize observer effects on individual organisms. However, in some instances the weight and resistance associated with telemetry tags have been shown to influence both organism behavior and survivability (Marcström *et al.*, 1989; Swenson *et al.*, 1999; Barron *et al.*, 2010). A common limitation of telemetry studies is the ability to capture and instrument enough animals for sound ecological inference on habitat selection.

Measurement of Environmental Variables

The characterization of habitat selection depends not only on the identification of organism locations but also the intersection of these locations with the environmental variables that define habitat. Environmental variables can be collected using field-based sampling or digital remote sensing. With some of the organism location methodologies described above (visual observation and some survey or trapping designs) environmental variables can be collected at the time the organism is located (e.g., Gutzwiller *et al.*, 1994). Though direct observation and measurement of environmental variables is still widely used in habitat selection research, another common technique for describing environmental variables at certain locations is digital remote sensing.

Digital data portraying environmental variables are now widely available for download from numerous reputable governmental and nongovernmental organizations. These data include digital elevation models, bathymetry data, hydrology, soil type, geologic features, vegetation cover, landuse data, climate, and many others. Therefore, some components of habitat can be compiled with relative ease using modern, often freely available data. Caution must be exercised when using widely available digital data so that the research question is properly framed and issues of scale are reconciled (Roloff *et al.*, 2009). For example, the data vintage must be consistent with the spatial and temporal positions of the organism location (Roloff *et al.*, 2009). If vintage of the environmental data are not considered, then the researcher will potentially describe environmental variables that the organism of interest was not necessarily selecting. Furthermore, spatial and temporal resolutions are also important factors to

consider (Roloff *et al.*, 2009). As discussed below (*see* Issues of Scale and Resolution) the resolution of the environmental data can limit the ability to make valid inferences. Spatial resolution refers to the minimum mapping unit in the data layer. Temporal resolution refers to the frequency of data collection or update. Regardless of the technique used for acquiring or compiling data on environmental variables, the resolution of the data must align with the spatial and temporal scales of selection for the organism of interest.

Analytical Techniques

Measurement of habitat use through mapping of animal locations and associated environmental variables is only the first part of describing habitat selection. The next step is to make inferences, or reach conclusions on the basis of evidence and reasoning. Numerous analytical techniques have been used to infer habitat selection. Models have been the cornerstone of habitat selection research for the last 30 years. Common modeling techniques can be based on organism presence/or abundance and the relationship between environmental covariates and organism locations, utilization distributions (UDs) as calculated from organism locations, or animal movements.

Linear and Logistic Regression Models

A common analytical approach in habitat selection research is to regress environmental variables (i.e., predictor variables) against a response variable that is either continuous (linear regression) or binary (logistic regression). Linear regression models typically take the form;

$$Y_i = \mathbf{x}'_i \boldsymbol{\beta} + Z_i$$

where Y is the response variable at location i , $\mathbf{x}$ is a vector of the environmental variables at location i , $\boldsymbol{\beta}$ is a vector of the regression parameters, and Z accounts for the random error term. The random error term can have spatial and temporal dependencies that should be accounted for (Ver Hoef *et al.*, 2001). A common response variable in linear regression models is a count of the individuals that occupy an area. Within these models there is a tacit assumption that more individuals in an area represent greater selection for the corresponding environmental variables associated with that area. The interpretation of the parameter estimates that are output from these models is based on the expected amount of change in the response (organism count) given unit changes in the environmental variables.

Logistic regression is generally used to model the relationships between presence or absence of an organism and environmental variables. Logistic regression models take the form:

$$P(y = 1 | \mathbf{x}) = \frac{\exp(\boldsymbol{\beta}'\mathbf{x})}{1 + \exp(\boldsymbol{\beta}'\mathbf{x})}$$

where the binary response variable is modeled given a value of 1 (presence or used), $\mathbf{x}$ is a vector of the environmental variables, and $\boldsymbol{\beta}$ is a vector of the regression parameters. Presence or use is based on measured organism locations whereas absence is often estimated. The creation of absence locations is a

topic that has been widely scrutinized (*see* How is Available Habitat Defined?). Absence locations in available habitat tend to be estimated via a random or stratified sampling design (Keating and Cherry, 2004). For example in a random design, absence is randomly assigned to locations in a study area, with the assumption that these locations are not used by the organism or that the locations portray what is available to the organism for selection. In a stratified design, absence is assigned to different locations based on some predetermined stratification, perhaps by vegetation or soil type. Selecting the sampling strategy that best suits the data depends on the research question, the species of interest, and the composition of environmental variables within the study area. Regardless of the technique that is selected, at each presence and absence location environmental variables are measured and model parameters are fit.

A specific type of regression modeling is referred to as resource selection functions. The goal of resource selection functions is to develop probabilities of relative use of environmental variables within the study area (Manly *et al.*, 2002). The classic use versus availability exponential model is expressed as;

$$w(\mathbf{x}) = \exp(\boldsymbol{\beta}_0 + \boldsymbol{\beta}_1 \mathbf{x}_1 + \boldsymbol{\beta}_2 \mathbf{x}_2 \cdots \boldsymbol{\beta}_k \mathbf{x}_k)$$

where $\mathbf{x}$ is a vector of k environmental variables and $\boldsymbol{\beta}$ is a vector of the coefficients at each location. This model is calculated with a logistic regression based on maximum likelihood estimation. The environmental variables can be either continuous or categorical, though similar to logistic regression, resource selection functions are subject to critique for the exact methodology employed to generate available locations (Boyce, 2006).

Utilization Distributions

UDs have been used to model habitat selection by departing from strict point-based modeling (Marzluff *et al.*, 2004). Essentially, UD stretch the probability of an animal occurrence across space and time. This technique improves on traditional home range estimators (e.g., minimum convex polygons) by recognizing that organisms use habitat nonuniformly. UD enable the researcher to quantify those environmental variables that are used more often than others.

The creation of a UD is initially informed by the collected organism locations. The organism locations are used to develop density estimates of relative use across spatial and temporal dimensions. Researchers typically divide their dataset of organism locations based on biological relevance and the question being asked (e.g., sex, season, year). The latitude (Y) and longitude (X) coordinates from organism locations are mathematically analyzed to develop the Z dimension in the UD, which represents the probability of space use. This probability of use can then be manipulated to function as the response variable in any modeling design. A variety of techniques can be implemented to measure the environmental variables within the UD. For instance Marzluff *et al.* (2004) developed a resource utilization function based on the entire UD. However, this procedure could prove computationally challenging for extremely large UD. Another option is to

implement a strategy for sampling the environmental variables within the UD (Marzluff *et al.*, 2004).

Animal Movement Models

One emerging area of modeling habitat selection is animal movement models. Given the potential for fine-scale temporal sampling from GPS telemetry tags, consecutive organism locations can be linked to simulate animal movement paths. Innovative new models incorporate temporal autocorrelation and can also be modified to integrate habitat availability within the context of an animal's UD while estimating model parameters via a Bayesian framework (Christ *et al.*, 2008). Furthermore, animal movement models can be fit using data collected at regular or irregular intervals (Johnson *et al.*, 2008). Animal movement models represent an exciting area of habitat selection research and have thus far proved integral to understanding migration patterns, responses to various time-sensitive phenomena (weather, temperature, disturbance events), and use of edge habitat (Schick *et al.*, 2008; Forester *et al.*, 2009; Morales *et al.*, 2010).

Inference

Among the scientific community, the term inference is used to describe the process of reaching logical conclusions based on evidence and reasoning. In habitat selection research inference is based on animal location and associated environmental variable data in an effort to understand organism decision-making. Inference from habitat selection research has resulted in formulation of multiple theories and concepts including niche theory (Petren, 2001; Hirzel and Le Lay, 2008), habitat suitability (Hirzel *et al.*, 2006), and specificity of habitat use (Devictor *et al.*, 2008). These theories and concepts have collectively added to our understanding of ecology.

The foundation of niche theory and resource partitioning includes a seminal publication by Joseph Grinnell in (1917) on the organism–habitat relationship for California thrashers (*Toxostoma redivivum*). Grinnell referenced a specific set of environmental variables that California thrashers were adapted to as ‘critical conditions.’ These conditions included humidity, slope, elevation, and composition of shrubbery. Grinnell (1917) posited that California thrashers were adapted to a specific set of environmental conditions and that the availability of these conditions limited distributional range, thereby defining niche. Later (in 1957), G. Evelyn Hutchinson formally articulated the multivariate components of habitat as an n -dimensional niche, where the n -dimensions correspond to different environmental variables that are used by the organism (Morrison *et al.*, 2006). Niche theory has been a useful construct to guide development of analytical tools for habitat selection research.

The concept of habitat suitability is based on Grinnell's notion that some portions of the niche are better suited for organism fitness than others, and that habitat selection can help reveal those relationships. The concept of suitability contends that habitat varies in quality, that is, some habitat is more conducive to occupancy, reproduction, and survival than others. Numerous analytical approaches have been used to portray habitat quality, including linear and logistic

regression, resource selection functions, UD, and an expert-opinion-based modeling approach called habitat suitability modeling (Singh *et al.*, 2009). These techniques portray disproportionate habitat use, with the assumption that areas receiving more use or having a higher probability of occupancy or use correspond to higher quality. However, animal density or occurrence is not always a reliable correlate to habitat quality (Van Horne, 1983) and researchers have emphasized the importance of using fitness (often quantitatively expressed as viability) as the best indicator of quality (e.g., Roloff and Hauffer, 2002; Mosser *et al.*, 2009).

Habitat suitability modeling has been conducted on a variety of species. One well-known example was performed in the mid 1990s. At that time it became clear that the wolf (*Canis lupus*) population in the Great Lakes region of the United States was growing rapidly. Concerned citizens, stakeholders, and scientists wanted to determine how widely wolves could potentially range. Mladenoff *et al.* (1995) developed a model that was used to map habitat suitability for wolves throughout the Great Lakes region. The model was built from habitat selection data collected on a population of well-studied wolves in northern Minnesota. The model was subsequently extrapolated to other areas in the Great Lakes region to estimate where wolves might colonize and survive. The research of Mladenoff *et al.* (1995) demonstrated, amongst other things, that wolves were capable of traversing large areas of unsuitable habitat in search of areas that provided the right mix of favorable habitat characteristics, a habitat use pattern that has been realized as wolf populations recovered in this region (Mladenoff *et al.*, 2009).

The occurrence, abundance, and fitness of some species are closely linked to specific environmental variables whereas other species exhibit more latitude in habitat selection. This observed difference in habitat specificity among species has resulted in two broad categories; habitat-specialists and habitat-generalists. Habitat-specialists are so suited to a specific set of environmental variables that they are vulnerable if these variables are altered. Habitat-generalists are more malleable in their dependence on specific environmental variables and can potentially thrive in disturbed habitat. In a world that is rapidly changing as a result of anthropogenic disturbance including human population growth, development, exploitation of natural resources, and accelerated climate change, habitat-specialists can experience significant population losses from habitat disturbance whereas habitat-generalists are more capable of adjusting to environmental change (Brook *et al.*, 2003).

Although the broad categories of habitat specialist and generalist imply autonomy, recent research has demonstrated that habitat functionality also depends on the composition of different species that occupy similar space and time. The term trophic cascade, for instance, describes an event where predators, at the top of the food chain, influence the vegetative community at the bottom of the food chain (Carpenter *et al.*, 1985; Ripple and Beschta, 2007). At the system level, predators are known to influence nutrient cycling through consumptive and nonconsumptive means (Bump *et al.*, 2009; Schmitz *et al.*, 2010). Furthermore, habitat heterogeneity and species diversity are positively associated (Tews *et al.*, 2004). Essentially, more varied environmental variables result in more potential niches and hence, greater species richness.

Limitations on Inference

How is Selection of Habitat Defined?

Point-based habitat selection models are built on the assumption that organism locations represent the full suite of selection decisions. In reality, sampling and technological shortcomings often limit, sometimes in a biased manner, the animal locations that are collected. For example, Beyer and Haufler (1994) demonstrated that inference on habitat selection by elk (*Cervus elaphus*) was different depending on whether the sample contained night-time locations. Technological advances, like modern GPS telemetry technology, have helped alleviate some of the logistical constraints associated with sampling. Indeed, use of GPS technology has revealed new insights into environmental variables that are infrequently used but nonetheless important (e.g., transitory areas between more highly used areas; Beyer *et al.*, 2010). However, GPS telemetry data do not represent a guaranteed solution as vegetation cover, weather, animal movement, and topography affect the likelihood of triangulating a position and the precision of the organism location. For example, topography is known to influence the ability of GPS to triangulate a location (Gantz *et al.*, 2006) and thus, resultant animal locations are biased to those areas where topography did not limit functionality of the GPS technology. By assuming that all organism locations in a data set represent the full suite of selection decisions, the importance of certain environmental variables is likely exaggerated whereas the value of others is likely diminished (Marzluff *et al.*, 2004). Hence, it is important for researchers to critically evaluate their animal location data, understand the spatial and temporal dimensions of the data, and adjust the scope of inference accordingly.

Another factor that limits our ability to make inference from habitat selection studies is the assumption that organisms are making selections for habitat that is ideal (i.e., organisms are free to choose among the full range of habitat conditions). Fretwell (1972) and Fretwell and Lucas (1969) described this process as the ideal free distribution. The concept implies that organisms are ideal in their perception of habitat and that they are free to choose among habitats. In reality, individuals are likely selecting less-than-ideal habitat because external pressures (e.g., dispersal constraints, intra and interspecies competition, source-sink dynamics, and human encroachment on habitat) limit the ability to perceive or move into ideal habitat. By studying organisms that are not behaving according to an ideal free distribution researchers risk identifying less than ideal habitat as ideal. This misidentification can have significant conservation ramifications if management activities inadvertently focus on less than ideal habitat. Herein lies the importance of using fitness as a metric of habitat suitability. Fitness should be highest in ideal habitats.

How is Available Habitat Defined?

Many logistic regression models and resource selection functions require the designation of available or presumably unused habitat. Because of the coarse temporal resolution characteristic of almost all animal sampling efforts, it is difficult

to say with certainty that available habitat were unused. For instance, an animal may make use of available habitat between sampling intervals. Thus, the naming convention representing the binary response is traditionally used versus available habitat. It is important to note that this is a problem which does not pertain to the habitat selection research of plants and fungi. Within this context it is possible to identify true absence locations by visiting various habitat and confirming plant presence or absence (Turner *et al.*, 2003). Methods for estimating available habitat in animal habitat selection research have been scrutinized (MacKenzie, 2005; Boyce, 2006). One technique for estimating available habitat is based on randomly sampling locations from the study area where organisms were not recorded (Edge *et al.*, 1987; Aebischer *et al.*, 1993). Another technique uses the organism locations to create a home range, and then samples available habitat within the home range (Anderson *et al.*, 2005; Christ *et al.*, 2008) (Figure 2). The aforementioned techniques are similar, yet the latter limits the generation of available habitat to only that within the organism's home range whereas the former allows sampling throughout the study area without considering the organism's site fidelity. The problems associated with identifying available habitat are often based on the delineation of the spatial and temporal boundaries of what is considered available.

Figure 2 Example of a use vs. availability design with a random sample of available habitat drawn from within the home range; (a) shows the organism locations collected by the researcher that were used to create the home range, whereas (b) displays the available locations which resulted from a random sample of all available habitat within the home range.

Depending on the method used to identify available habitat, the ability to infer ecological relationships can vary substantially. Porter and Church (1987) found that results from the same habitat model could contradict depending on the manner in which available habitat was portrayed. This facet of traditional experimental designs for assessing habitat use and availability injects uncertainty into the inferences derived from this research. The problem is that decisions on how to define habitat availability are commonly made *a priori*. Study area boundaries are identified as a result of funding, logistics, or the delineation of political demarcations, none of which may be relevant to the biology of an organism. Despite this reality, study areas are one of the primary means by which habitat is considered available.

There is also an assumption that areas without recorded animal locations represent unselected habitat. The limitations of different organism location techniques (e.g., organisms can only be observed during certain times of day, measurement error), coarse temporal resolution of some telemetry data, and problems with detection probability influence whether the researcher is able to definitively designate available habitat as definitively unused. While measuring habitat selection, the probability of detecting organisms of interest can vary. Historically, researchers have assumed that detection probability was reliable and constant. In reality, conditions during measurement of habitat selection (vegetation cover, weather, animal behavior, and observer bias) can influence the researcher's ability to detect an organism. Failure to account for imperfect detection probability can impact inferences derived from habitat selection research (MacKenzie *et al.*, 2006). For instance, the importance of habitat where an organism is readily detected can be overestimated whereas habitat where the organism occurred but was not detected would be undervalued. However, once the probability of detecting an organism is calculated, this probability can be incorporated into models developed to quantify habitat selection (MacKenzie *et al.*, 2006). Regardless, near-continuous telemetry sampling or intense visual observation would be required to completely assuage this critique associated with how available habitat is defined.

Furthermore, there is an important spatial and temporal component to identifying what should be considered available habitat which can be referred to as habitat accessibility (Buskirk and Millsaugh, 2006). For example, if a sedentary organism is selecting habitat in the far western portion of its home range, then habitat 5 km away cannot be simultaneously considered available. Researchers must explicitly consider both habitat availability and accessibility in their habitat selection research to increase the validity of their inferences.

Issues of Scale and Resolution

Scale is critical to any examination of habitat selection. The components of scale include extent and resolution. Extent defines the boundary of the analysis; resolution refers to the smallest identifiable unit (also referred to as grain and minimum mapping unit). Inference derived from habitat selection research can vary depending on extent (*see* How is Available Habitat Defined?) and resolution (e.g., see Roloff *et al.*, 2009). Thus, an understanding of scale as it relates to the biology of

the study organism and the research question is critical for valid inference (Turner *et al.*, 2001; Roloff *et al.*, 2009). Furthermore, ecological processes exhibit spatial and temporal variabilities and the results and inferences derived from habitat selection research directly depend on the scale of the analysis (Boyce, 2006).

Johnson (1980) articulated that organisms perceive their environment at varying scales and make decisions to satisfy certain life history events in orders that depend on these scales (Figure 3). The first-order represents a selection of habitat that defines the range of the species. Selection of habitat by individuals for the placement of home ranges within the species range occurs at the second-order. The third-order of the hierarchy represents within home range selections, for example, denning, feeding, or roosting areas, whereas the fourth-order addresses fine-scale (e.g., microsite, daily) habitat selections.

As organisms use their environment at varying spatial and temporal scales, failure to explicitly consider scale can distort inference. In a habitat modeling framework, scale affects the relationship between the response variable(s) and the environmental variables that describe the habitat. For instance, certain habitat selection studies divide the study area (extent) into a network of polygons, called habitat units (e.g., a grid lattice of polygons delineated at a specific resolution) (Servheen and Lyon, 1989; Boyce *et al.*, 2003). When habitat selection research depends on concepts like habitat units, identifying the scale of those units must be done in careful consideration of the research question, the biology of the organism, and the patterns and processes of the environment. Furthermore, it is recommended that several different scales be examined and model selection methods be utilized to identify the best-approximating model (Anderson *et al.*, 2005; Boyce, 2006).

Spatial and Temporal Autocorrelation

Spatial and temporal autocorrelations are two factors that influence the measurement of habitat selection. Autocorrelation can be viewed as the similarity among observations as a function of the space or time separation among them. Regression models have a statistical structure that requires independence of the environmental variables. As environmental variables (e.g., elevation, vegetation type, and soil structure) are more similar to one another in space and time the fine-scale sampling protocols associated with acquisition of some animal location techniques (e.g., direct visual observation, GPS telemetry) will yield data that exhibit correlated, directional dependencies. Failure to account for these inherent dependencies is a violation of regression model assumptions.

The issue of autocorrelation in space and time has direct ramifications on inference because failure to account for dependencies amongst the environmental variables imputes bias into the model design, potentially inflating the significance of certain relationships. The problem is that a researcher could infer an organism–habitat relationship that is stronger than it is in actuality, simply because a facet of the modeling design was neglected. However, regression models and RSFs can be structured to account for autocorrelations. As mentioned, a progressive area of habitat selection research involves the

Figure 3 Four orders of hierarchical habitat selection outlined by Johnson (1980); (a) the first-order selection represents habitat selection that defines the range of the species, in this case the range of the white-headed woodpecker (*Picoides albolarvatus*). (b) in the second-order selection an individual white-headed woodpecker makes a selection for the placement of their own home range within the species range. (c) the third-order selection correspond to within-home range habitat selection, and (d) the fourth-order selection relate to fine-scale daily habitat selection.

integration of autocorrelation within animal movement models. When autocorrelation is explicitly included into the likelihood method of estimating model parameters more accurate interpretations of ecological relationships become possible (Boyce *et al.*, 2010).

Locational Imprecision

The unprecedented depth and scope of our ability to locate organisms, particularly with telemetry systems have fostered the assumption that measured organism locations are precise. In actuality, locational data can have considerable amounts of measurement error which is problematic for habitat selection research. In 1990, Gary White and Robert Garrott published an important book which, amongst other things, demonstrated the necessity of explicitly incorporating measurement error into habitat selection models. Given that habitat selection research strives to understand which habitat patches an individual is using in relation to those that are available, measurement error limits our ability to accurately detect true organism–habitat associations. White and Garrott summed up this sentiment when they wrote that habitat selection models “require a precise estimate of an animal’s location so that it can be correctly placed in a habitat type” (White and Garrott, 1990:200). Without precise locations habitat selection models have the potential to produce erroneous results. Following White and Garrott (1990) numerous methods (e.g., ignoring the error, rescaling environmental variables, majority sampling, and bivariate-weighted techniques) were developed to explicitly incorporate measurement error into habitat selection models. For several decades these techniques

were applied to habitat selection research. However, the ability of these techniques to ameliorate the error associated with organism locations had rarely been tested.

Montgomery *et al.* (2010) demonstrated that commonly used techniques for incorporating error into habitat selection studies were largely incapable of accurately portraying habitat use. However, by 2010 the primacy of VHF technology had been usurped by GPS telemetry data. GPS data are, on the whole, more accurate than VHF data with errors that are commonly < 12 m, depending on topography, canopy cover, and geographic location (Cargnelutti *et al.*, 2007). Because of this documented precision, a common approach was to simply ignore the measurement error and proceed with the modeling design assuming that the organism locations were near perfect. Montgomery *et al.* (2011) examined the effects of ignoring measurement error consistent with GPS telemetry systems. Their analysis discovered that ignoring measurement error from precise telemetry systems could have considerable ramifications on the ability to make valid habitat selection inferences. Regardless, new models and analytical methodologies are frequently being designed to portray habitat selection with as little bias as possible. The progression of telemetry technology from the 1950s forward demonstrates that habitat selection research is ever-evolving, constantly advancing on what has been done previously with new techniques and innovative methodologies.

Conclusions

It is doubtful that the nineteenth century naturalists who painstakingly recorded organism–habitat associations through

visual observation could have possibly conceived of the technological advances that currently inform habitat selection research. Researchers have moved from hours spent every day in the field collecting data to mere seconds at the computer engaged in the very same activity. Nevertheless, the quest to understand ecology remains the same. The prospect of elucidating the ecology of an individual which might characterize a population or even the species itself has proved completely absorbing. In this effort researchers have made important technological innovations and have developed new and interesting models to describe habitat selection. These collective advances have led to a vast progression of the discipline of habitat selection research.

The relationship between organisms and their habitats is considered integral to species survivability and the inferences garnered from habitat selection research have informed management and policy decisions. This information is particularly useful in the dynamic twenty-first century where threats to environmental change are ubiquitous and persistent. There is no doubt that further technological and quantitative innovations will be an integral part of the continued development of habitat selection research.

Indicator Species: Computation

Pierre Legendre, Université de Montréal, Montréal, QC, Canada

© 2013 Elsevier Inc. All rights reserved.

Glossary

Fidelity The degree to which a species is present at all sites of a group.

Indicator species A biological species that has a high indicator value for a group of sites. In the Indicator value method, species j is an indicator of group of sites k if the indicator value of species j is the highest, among all groups, for that group of sites, and is statistically significant at a preselected significance level.

Indicator value The degree to which a species is indicator of (the conditions found in) a group of sites.

Pseudospecies To model the concept of differential species (i.e., species with clear ecological preferences),

which is qualitative, TWINSpan creates pseudospecies. Each species is recorded into a set of dummy variables, called pseudospecies, corresponding to relative abundance levels (or percentage cover for plants) at each site; these classes are cumulative. If the pseudospecies cutting levels are 1%, 11%, 26%, 51%, and 76%, for instance, a relative abundance of 18% at a site will occupy the first and second dummy pseudospecies vectors with "1" (=presence). Cutting levels are arbitrarily decided by users. A (sites $\times$ pseudospecies) data table is created.

Specificity The degree to which a species is found only in a given group of sites.

Ecological Interest for Indicator Species

How to identify characteristic or indicator species is a traditional problem in community ecology and biogeography. It is grounded in the paradigm that species are the best indicators available for particular environmental conditions. Field studies describing habitats or groups of sites often mention one or several species that characterize each habitat. Because indicator species add ecological meaning to site groups discovered by clustering, they provide criteria to compare typologies derived from data analysis, to identify where to stop dividing clusters into subsets, and to point out the main levels in a hierarchical classification of sites. Indicator species differ from species associations in that they are indicative of particular, predetermined groups of sites. Good indicator species should be found mostly in a single group or a limited number of groups of a typology, and be present at most of the sites belonging to that or these groups. This duality is of ecological interest; yet it is not always used in indicator species studies.

There is clearly a need for the identification of characteristic or indicator species in the fields of monitoring, conservation, and management. For example,

- Species may be used as indicators of the state of an ecosystem and of human-induced changes to the environment and biodiversity.
- In long-term environmental follow-up studies for conservation or ecological management, researchers are looking for biological indicators of habitat types or combinations of habitat types they want to preserve or rehabilitate (McGeoch and Chown, 1998).

As for many other ecological concepts, the empirical method of early ecologists who walked through ecosystems and examined data tables to identify indicator species has gradually been replaced by statistical methods that attempt to reproduce and formalize the reasoning of the traditional

ecologists, with computer programs facilitating the calculations. In this article, the author will focus on statistical methods for the identification of indicator species, comparing the merits of the Two-way indicator species analysis (TWINSpan) and Indicator value (IndVal) methods.

Statistical Methods: TWINSpan and IndVal

TWINSpan: A Brief View

Two-way indicator species analysis (TWINSpan) (Hill, 1979) is fundamentally a method for hierarchical divisive classification of communities, based on progressive refinement of a single ordination axis obtained by correspondence analysis (CA) or detrended correspondence analysis (DCA) of a community composition (sites $\times$ species) data matrix. The algorithm, which is rather complex, is detailed by Kent and Coker (1992). An attractive feature of the computer output is a two-way table with the sites (columns) sorted according to the splits of the hierarchical classification. The species (rows) are also sorted so as to form blocks corresponding to the groups of sites of the classification. The body of the table contains the highest pseudospecies scores (see Glossary) found at the sites.

An additional feature of TWINSpan is that it computes an indicator values index (I) for the species for every split of the hierarchical classification of the sites. According to Kent and Coker (1992), the index is computed as follows using the pseudospecies data (see Glossary):

$$I_j = \frac{n_j^+}{n^+} - \frac{n_j^-}{n^-}$$

where n^+ and n^- are, respectively, the number of sites on the (arbitrarily chosen) positive and negative sides of the split, whereas n_j^+ and n_j^- are the number of sites on the positive and negative sides, respectively, that contain pseudospecies j .

A pseudospecies present in every site on the positive side and in none of the sites on the negative side obtains $I_j=1$, and -1 if it is found in every site on the negative side and in none on the positive side. A pseudospecies that occurs in all sites on both sides of the split obtains $I_j=0$. In TWINSpan, only one pseudospecies of a single species is declared an indicator of a split, and that is the pseudospecies that has the highest absolute value of I . n_j^+/n^+ is the measure of fidelity to a group used in the INDVAL method (see The INDVAL Method).

The major disadvantage of TWINSpan is that it can only compute the indicator value of species for the hierarchical classification produced by itself. Another critique is that the importance of a species in the analysis depends on the abundances of the other species because the pseudospecies, which form the data basis of the method, are based on species relative abundances. The method has also been criticized by Belbin and McDonald (1993) because it assumes the existence of a single, strong gradient dominating the data structure, and because the cutting points for the whole group, and then for subgroups, are always chosen to be the centroid of the group to be split instead of a point where a large gap occurs in the data. Because of that, sites that are very similar in species composition may end up in separate groups. The last problem has been alleviated by a modification to the method proposed by Roleček *et al.* (2009).

The INDVAL Method

Dufrêne and Legendre (1997) presented an alternative to TWINSpan in the search for indicator species and species assemblages characterizing groups of sites. Like TWINSpan, the indicator value (INDVAL) method analyses the species with reference to a prior partition of the sites. The first novelty of INDVAL is that it derives indicator species from any hierarchical or nonhierarchical classification of the objects (sampling sites), contrary to TWINSpan where indicator species can only be derived for a classification obtained by splitting sites along a CA axis. The second novelty lies in the way the indicator value of a species is measured for a group of sites. The indicator value index (INDVAL) is based only on within-species abundance and occurrence comparisons; its value is not affected by the abundances of other species. The significance of the indicator value of each species is assessed by a randomization procedure.

The INDVAL index is defined as follows. For each species j in each cluster of sites k , one computes the product of two values, A_{kj} and B_{kj} . A_{kj} is a measure of specificity based on abundance values whereas B_{kj} is a measure of fidelity computed from presence data:

$$A_{kj} = N_{\text{individuals}_{kj}} / N_{\text{individuals}_{+k}}$$

$$B_{kj} = N_{\text{sites}_{kj}} / N_{\text{sites}_{k+}}$$

$$\text{INDVAL}_{kj} = A_{kj} B_{kj}$$

In the formula for specificity (A_{kj}), $N_{\text{individuals}_{kj}}$ is the mean abundance of species j across the sites pertaining to cluster k and $N_{\text{individuals}_{+k}}$ is the sum of the mean abundances of species j within the various clusters. The mean number of individuals in each cluster is used, instead of summing the individuals across all sites of a cluster, because this removes

any effect of variations in the number of sites belonging to the various clusters. Differences in abundance among sites of a cluster are not taken into account. A_{kj} is maximum when species j is present in cluster k only. In the formula for fidelity (B_{kj}), $N_{\text{sites}_{kj}}$ is the number of sites in cluster k where species j is present and $N_{\text{sites}_{k+}}$ is the total number of sites in that cluster, as in index I of TWINSpan. B_{kj} is maximum when species j is present at all sites of cluster k . Quantities A and B must be combined by multiplication because they represent independent information (i.e., specificity and fidelity) about the distribution of species j .

The indicator value of species j for a partition of sites is the largest value of INDVAL_{kj} observed over all clusters k of that partition:

$$\text{INDVAL}_j = \max[\text{INDVAL}_{kj}]$$

The index is maximum (its value is 1) when the individuals of species j are observed at all sites belonging to a single cluster. A random permutation procedure of the sites among the site groups is used to test the significance of INDVAL_j . A correction for multiple testing is necessary before reporting the results when multiple tests (for several species) have been conducted. The index can be computed for a given partition of the sites, or for all levels of a hierarchical classification of the sites.

Numerical Example

Table 1 describes the example given by Dufrêne and Legendre (1997), slightly modified, to illustrate the computation of the INDVAL index. The data represent three species observed at 25 sites, which are divided into five groups. To facilitate comparisons, the sums of the mean group abundances are 20 for all three species. For species 1, INDVAL_{k1} has the highest value (0.30) for group 2, so $\text{INDVAL}_1=0.30$. Following similar reasoning, $\text{INDVAL}_2=0.40$ and $\text{INDVAL}_3=0.90$. The permutational p -values computed by functions `INDVAL()` of LABDVS and `multitip()` of INDICESPECIES in R are significant in all three cases.

Statistical Method: INDVAL Expanded

De Cáceres and Legendre (2009) described other statistics that can be used to assess the indicator value of species. The statistics are divided into (1) correlation indices, which are used for determining the ecological preferences of species among a set of alternative site groups or site group combinations, and (2) indicator value indices, including INDVAL, which are used for assessing the predictive values of species as indicators of the conditions found in site groups, for example for field determination of community types or ecological monitoring. Each of these families of indices comes in different types: there are indices for presence-absence and for quantitative species data; there are also nonequalized indices that give equal weights to individual sites and group-equalized indices that give equal weights to all groups whatever the number of sites they contain. For studies involving several groups of sites, De Cáceres *et al.* (2010) showed that the interpretation of indicator value analysis could be improved by computing the statistics for all possible

Table 1 Numerical example: abundance of three species at 25 sites divided into five groups

Groups	Group 1					Group 2					Group 3					Group 4					Group 5				
Sites	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20	21	22	23	24	25
Species 1	4	4	4	4	4	6	6	6	6	6	5	5	5	5	5	3	3	3	3	3	2	2	2	2	2
Species 2	8	8	8	8	8	4	4	4	4	4	6	6	6	6	6	4	4	2	0	0	0	0	0	0	0
Species 3	18	18	18	18	18	2	2	2	2	2	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0

Species 1

A_{k1}	4/20=0.20					6/20=0.30					5/20=0.25					3/20=0.15					2/20=0.10				
B_{k1}	5/5=1					5/5=1					5/5=1					5/5=1					5/5=1				
$IndVal_{k1}$	0.20					0.30					0.25					0.15					0.10				

Species 2

A_{k2}	8/20=0.40					4/20=0.20					6/20=0.30					2/20=0.10					0/20=0.00				
B_{k2}	5/5=1					5/5=1					5/5=1					3/5=0.6					0/5=0				
$IndVal_{k2}$	0.40					0.20					0.30					0.06					0.00				

Species 3

A_{k3}	18/20=0.90					2/20=0.10					0/20=0.00					0/20=0.00					0/20=0.00				
B_{k3}	5/5=1					5/5=1					0/5=0					0/5=0					0/5=0				
$IndVal_{k3}$	0.90					0.10					0.00					0.00					0.00				

Top panel: species abundance data. Bottom: calculation of the specificity (A_{kj}), fidelity (B_{kj}) and $IndVal_{kj}$ index for each species (j) in each group of sites (k). The maximum value of $IndVal_{kj}$ for each species is in bold.

combinations of site groups. Moretti *et al.* (2010) published an application of that method.

A detailed discussion of the limitations of indicator value analysis is found in De Cáceres *et al.* (2010). They point out that more indicator species will be found than expected by chance when the classification of sites was obtained from the same species composition data that are used for IndVal analysis. In that case, p-values must be interpreted with caution: they do not result from a genuine test of significance where the classification of sites has to be independent of the species data used in the test.

Variants of the *IndVal* index have been proposed by Podani and Csányi (2010). Instead of using specificity and fidelity alone, these authors proposed to define the indicator value of a species as the product of two among three quantities: specificity A_{kj} (that they called concentration), specificity (new equation, with allowance for positive or negative species preferences), and fidelity B_{kj} . They provided formulas based on presence-absence or abundance data for each of these three quantities.

According to McGeoch and Chown (1998), *IndVal* is important for conservation biology because it is conceptually straightforward and allows researchers to identify biological indicators for any combination of habitat types or areas of interest – existing conservation areas, or groups of sites based on the outcome of a classification procedure. The method is sometimes used to identify biological indicators for groups of sites classified using the target taxa, subject to the caveat about p-values mentioned two paragraphs up, or in other instances using nontarget taxa, for example finding insect biological indicators for a classification of sites based on plant community data.

An *IndVal* index for a species is calculated independently of the other species in the assemblage. Because of that, comparisons of indicator values can be made between taxonomically unrelated taxa, or taxa in different functional groups or in different communities. Comparisons across taxa are robust to differences in abundance that may or may not be due to differences in capturability or sampling methods. The method is also robust to differences in the numbers of sites between site groups, in abundance among sites within a particular group, and in the absolute abundances of very different taxa that may show similar trends.

When a group of sites for which indicator species are sought corresponds to a well-delimited geographic area, superposition of distribution maps for the indicator species of that group should help identify the core conservation areas for these species, even when little other biological information is available.

Taxa described as biological indicators in the literature are often merely the favorite taxa of their proponents; ornithologists prefer birds, lepidopterists butterflies, and coleopterists beetles. *IndVal* provides an objective method for addressing this problem by enabling assessment of the relative merits of different taxa for a given study area (McGeoch and Chown, 1998). The species that emerge from this procedure as the best indicators for a group of sites should prove useful for monitoring site alterations, natural or man-induced.

Ecological Applications

Carabid Beetles in Belgium

Dufrêne and Legendre (1997) analyzed a large data set of Carabid beetle distributions in open habitats of Belgium

(189 species collected in pitfall traps at 69 sites). Classification of the sites was obtained by distance-based *K*-means partitioning computed as follows: first, a distance matrix (percentage difference, also called Bray-Curtis distance) was computed from the log-transformed species abundance data; this distance matrix was subjected to principal coordinate analysis (PCoA), also called metric multidimensional scaling; all ordination axes (i.e., the principal coordinates) produced by PCoA were used as input data into *K*-means partitioning. Although the clusters produced by *K*-means were not forced to be hierarchically nested, they showed a strong hierarchical structure for *K*=two to ten groups. This allowed the authors to represent the relationships among partitions as a dendrogram with *K*=10 groups, which corresponded to the main types of habitat recognized *a priori* by surveying the sites.

Indicator values were computed for each species and partitioning level. Some species were found to be stenotopic (narrow niches) whereas others were eurytopic (species with wide niches, present in a variety of habitats). Other species characterized intermediate levels of the hierarchy. The best indicator species (*IndVal*>0.25) were assembled into a two-way indicator table; this tabular representation displayed hierarchical relationships among the species.

The *INDVAL* results were compared to *TWINSPAN*. The partitions of sites used in the two methods were not the same; the *TWINSPAN* typology was obtained by partitioning CA ordination axes. *TWINSPAN* identified, as indicators, pseudospecies pertaining to very low cut-off levels. These species were not particularly useful for prediction because they were simply known to be present at all sites of a group. Several species identified by *TWINSPAN* as indicators also received a high indicator value from the *IndVal* procedure for the same or a closely related habitat class. *IndVal* identified several other indicator species, with rather high indicator values, that also contributed to the specificity of the groups of sites but had been missed by *TWINSPAN*. So, the *IndVal* method appeared to be more sensitive than *TWINSPAN* to the fidelity and specificity of species.

More Application Examples

Here are more examples of the many applications of indicator species analysis found in the literature.

- Borcard (1996) and Borcard and Vaucher-von Ballmoos (1997) present applications of the indicator value method to the identification of the Oribatid mite species that characterize well-defined zones in a peat bog of the Swiss Jura.
- The indicator values of beetle species characterizing different types of forests have been studied by Barbalat and Borcard (1997).
- Tuomisto *et al.* (2003) used spatially-constrained clustering to group 86 sampling units, each 500 m in length, forming a 43-km long transect in the Amazonian rain forest in Peru, into spatial clusters on the basis of satellite image pixel values. They also surveyed the ferns and Melastomaceae in the 86 sampling units in the field. Then they used the *INDVAL* method to determine the species of ferns and Melastomaceae that were good indicators of the spatial clusters.
- Legendre *et al.* (2009) used multivariate regression tree analysis (De'ath, 2002) to identify habitat types that were similar in topographic conditions and in species composition in a Chinese permanent forest plot divided in 20 m × 20 m quadrats; then they used the *IndVal* method to identify, among the 159 tree species, the nine species that were statistically significant indicators of the five main habitat types. In this paper, the species used for *IndVal* analysis had been used to obtain the classification of the sites; as a consequence, the *p*-values had to be interpreted with caution.
- De Cáceres *et al.* (2010) carried out indicator species analysis of the vegetation of the Barro Colorado Island (BCI) permanent forest plot in Panama, also divided in 20 m × 20 m quadrats, grouped into seven habitat types identified in the literature. Among 307 tree species, they identified 44 indicator species of individual habitat types and 64 species for habitat type combinations. In this paper, the classification of the sites was independent of the species analyzed for indicator value.

Conclusion

Indicator species are biological indicators of groups of sites representing habitat types or combinations of habitat types; they are of prime interest for ecosystem conservation and management. Statistical methods are now available to identify indicator species in different situations (presence-absence or abundance data, group-equalized or nonequalized indices) and for a variety of purposes: correlation indices are used for determining the ecological preferences of species among a set of alternative site groups or site group combinations, whereas indicator value indices are used for assessing the predictive values of species as indicators of the conditions found at groups of sites. Both types of indices are readily available for computation in R functions. Tests of significance can be computed for these indices, producing *p*-values that help identify the most interesting indicator species.

Software

In the R statistical language, indicator value indices (*INDVAL*) can be computed by functions *strassoc()* and *multipatt()* of *INDICESPECIES* and by function *indval()* of *LABDSV*. The functions in *INDICESPECIES* offer a choice of the several different indicator statistics described in De Cáceres and Legendre (2009). The *INDVAL* index is also available in the computer package *PC-ORD*. The *TWINSPAN* program, in *FORTRAN*, can be obtained from several Web pages.

Glossary

Abundance The number of individuals of a given species in a region.

Estimator A statistic calculated from data to estimate the value of a parameter.

Incidence The number of samples containing at least one of a given species in a census.

Sampling scope The area, interval of time, and taxonomic grouping over which sampling takes place.

Spatial heterogeneity In community sampling, variation in species capture probabilities across space; may be due to habitat variation, intraspecific clumping, interspecific association, or other factors.

Species abundance distribution The number of species found in each interval of abundance in a community.

Species accumulation curve A plot of the total number of species observed in a census against some measure of cumulative sampling effort.

Species diversity Any of many measures concerning the number of species in an area and/or the distribution of their abundances.

Species richness The number of species present in a region.

Temporal heterogeneity In community sampling, variation in species capture probabilities over time; may arise from temporal environmental variation, migration, speciation, or other factors.

Introduction

Why Measure Diversity?

Biological diversity pervades every aspect of community ecology. As the key distinguishing feature of communities, it forms the basis of many ecological studies. Many studies have used a wide range of techniques to quantify diversity. These have included studies focused on patterns of species number in both time and space. Projects with more mechanistic aims have employed diversity measures to draw inferences about processes influencing diversity (e.g., migration, habitat selection, and competition at ecological timescales; and speciation, colonization, and extinction over evolutionary scales). The measurement of diversity applies to studies of the potential consequences of diversity (e.g., stability and resistance to invasion). In addition, diversity measurement plays a critical role in the study of human impacts on biological systems. Its uses in conservation include estimation of extinction rates due to habitat loss, development of conservation strategies, indication of effect due to disturbance, and use as a barometer of ecosystem status. These and other fields of inquiry require adequate methods for quantifying species diversity.

Measures of Diversity

Diversity measures are classified into two broad categories: species richness (SR) and shape of the species abundance distribution. The first simply reflects the number of species present in an area. The second effectively measures the probability distribution of population sizes of the species in an area. Evenness and equitability measures belong to the second category. Evenness is highest when all abundances have equal probability in a certain range, whereas equitability is highest

when all species have the same population size. Depending on the question under investigation, both categories of diversity measures may be used to document patterns. Many hypotheses concerning patterns in diversity use the relatively simple concept of SR to make concise statements connecting pattern and process. Although richness simply refers to the number of species, it encompasses many sophisticated issues in sampling design and estimation. For these reasons, most studies use species richness. We restrict our focus to species richness as well.

The Problem

Species richness, the number of species present, is conceptually the most straightforward of diversity measures. Measuring richness, however, is not so simple. The number of species observed in a sample, S_{obs} , will always tend to underestimate the true species richness because we lack the resources for exhaustive sampling of communities. Even if we had such resources, properties of community structure may change during the course of sampling. This problem is exacerbated by the fact that many biological communities have many rare species, which are unlikely to be detected by sampling efforts. These issues are not unique to ecology.

The problem of determining the number of classes of objects in a collection has a long history. Many different disciplines have sought ways to estimate the number of undiscovered classes from the classes already observed. For example, how many dies were used to mint a collection of ancient coins? How many undiscovered bugs remain in a large computer program? No one method has been successful with all such problems because we often find that we have the most information where it is the least useful. That is, a few classes account for most of the observations, whereas a few

observations are scattered over most of the classes. Therefore, we wind up with small sample sizes for the rare observations where we need to characterize variation the most. In the most extreme case, imagine a community in which every species is represented by just one individual. Then, for any sample size below the true number of species we shall always observe fewer than the true number of species. Of course, in this case we could observe that the number of species was a linear function of the number of individuals. This might suggest to us a way to estimate the number of undetected species if we knew how many individuals were present in the study area. This example illustrates the strategy followed by richness estimators: Model the regularity in the behavior of the number of species detected as a function of sample size. Then, use this model to predict the number of species when the sample size becomes large. The regularity could involve a clear relationship between the average sample size and the average number of species observed; this is the basis of extrapolation-based estimators. On the other hand, the regularity could mean that we can replace a complicated sampling process with a more tractable model; estimators based on sampling theory follow this approach.

Article Overview

An exhaustive review of all methods used for estimations of species richness is beyond the scope of this article. Therefore, this article reviews the most widely used methods for the estimation of species richness. *Definition of Symbols* defines the symbols used in this article. *Theoretical Properties of Richness Estimators* lists some theoretical properties of richness estimators. *Practical Sampling Considerations* discusses practical considerations of using community sampling to estimate species richness. The next two sections present the estimators: richness estimators based on fine-scale, theoretical models of sampling are detailed in *Estimators Based on Sampling Theory*, whereas those based on coarse-scale, global modeling of species accumulation (extrapolation techniques) are discussed in *Estimators Based on Extrapolation*. *Which Estimation Method to Use?* addresses the practical problem of evaluating and selecting estimators for use on new data sets.

Definition of Symbols

We adopt the convention that random variables are written as uppercase symbols, whereas lowercase is reserved for deterministic variables or fixed constants. The definitions we shall need are given in Table 1.

Theoretical Properties of Richness Estimators

Salient features of richness estimators include the following:

Type of data: Estimators differ in whether they use incidence or abundance data. The incidence of species i is the number of samples in which i occurs. Formally, $Y_i = \sum_{j=1}^t Y_{ij}$. The abundance of species i is the number of individuals of i contained in the census. Formally, $X_i = \sum_{j=1}^t X_{ij}$.

Table 1 Symbols Used

s	Number of species in a community
n	Number of individuals in a community
x_i	Number of individuals of species i in a community
r_i	Number of species with i individuals in a community
S_{obs}	Number of species in a census
S_{est}	Estimate of the number of species in a community using given method
N	Number of individuals in a census
C	The sample coverage of the census
t	Number of samples in a census
X_i	Number of individuals of species i in a census
X_{ij}	Number of individuals of species i in sample j
Y_i	Number of samples containing species i in a census
Y_{ij}	The presence (1) or absence (0) of species i in sample j
R_i	Number of species containing exactly i individuals in a census
F_i	Number of species occurring in exactly i samples in a census
P_i	Probability of detecting species i in a sample
q_i	Probability that an individual is of species i
$I(\omega \in A)$	1 if $\omega \in A$ and 0 otherwise
$E[X]$	The expectation of the random variable X
$\text{VAR}[X]$	The variance of the random variable X
$\text{COV}[X, Y]$	The covariance of the random variables X and Y
$\text{CORR}[X, Y]$	The correlation of the random variables X and Y
$\gamma(Z)$	Coefficient of variation of the random variable Z

Sampling assumptions: Many estimators make assumptions about the sampling process (e.g., invariance of capture probabilities across all samples in a census).

Parametric/nonparametric: The estimator $S_{\text{est}} = \psi(X)$ is nonparametric if the function ψ does not depend on a given distribution of X .

Bias: Bias measures average deviation from the true value. We define $\text{bias} \equiv E[\psi(X)] - s$. An estimator of s is unbiased in the strict statistical sense if $E[\psi(X)] - s = 0$ for every s .

Variance: An estimator is a random variable. Therefore, we can use variance as a measure of the uncertainty in an estimate.

Sufficiency: Let $w = \psi(x)$ be an estimator of s . The statistic $W = \psi(X)$ is sufficient for s if $P\{X \in A | W, s\} = P\{X \in A | W\}$. Suppose $S_{\text{est}} = \psi(X)$ is sufficient for s . Then there are no other estimators (other than functions of ψ) that we could compute using X that could increase or decrease our confidence about our estimate of s .

Practical Sampling Considerations

Limiting the Influence of Sampling Biases

We lack the resources for complete censusing of communities. Thus, sampling is the window through which we view the ecological world. The species we observe when we sample are determined both by underlying ecological processes and by biases associated with sampling. The simplest of these is bias due to sample size. If we plot the number of species observed

Figure 1 The species accumulation curve for a simulated data set. Note the nonlinear trend in the increase of species observed with increasing sample size.

in a census against some measure of sampling effort, such as individuals counted, we get a species accumulation curve as shown in **Figure 1**. Sample size bias accounts for much of the increase in a species accumulation curve with increasing sampling effort. This bias may be reduced by increasing sample size or by estimating the number of species actually present from incomplete census data. An increase in the accumulation curve also arises from sampling over different habitats and at different times. Spatial and temporal heterogeneity are difficult to quantify, as are their effects on the performance of richness estimators. It may be possible, however, to reduce such effects through careful sampling design. As a general rule, one should minimize sources of variation in capture probabilities over sampling. Where possible, the spatial and temporal scale of a census (see *Practical Sampling Considerations: Sampling Scope*) should be small relative to the scale of the processes generating diversity.

Sampling Scope

Any sampling effort can be described as taking place within some area, over an interval of time, and involving a particular taxon or group of taxa. Even within the area sampled, some habitats may not be sampled. Likewise, within an interval of time, some periods are often not considered (e.g., sampling that takes place over a week but never at night). We define sampling scope as the area (and habitats) sampled, the interval of time (and periods within that interval) over which sampling occurred, and the group of taxa sampled. The consideration of sampling scope is important because it means that the sampling design must be tailored to the question of interest.

The number of species predicted by richness estimators reflects the scope of sampling. In general, these methods estimate only the number of species in the taxa, area, and time interval sampled.¹ For example, estimates from ground-level plant surveys do not predict epiphyte diversity. Similarly, daytime sampling does not predict nocturnal animal species, estimates based on beetle abundance do not predict ant diversity, summer bird diversity does not inform us of winter migrants, and so on.

Abundance and Incidence

With quadrat-based sampling, the area to be sampled is partitioned into many subsamples (quadrats) of equal size. A subset of t of these quadrats is then sampled using capture or observation techniques appropriate for the taxon of interest. The data recorded may take the form of either species incidences Y_{ij} or abundances X_{ij} .

Abundance data may not be possible to collect in all cases. For some taxa (e.g., some fungi), individuals are not readily recognizable as such. Additionally, some sampling methods may not allow abundances to be recorded. For example, point counts based on bird vocalizations are a practical method of recording species in bird communities but do not allow accurate counting of individuals. Even when abundances can be observed, obtaining abundances may require more effort than obtaining incidences alone. Nonetheless, a wider range of estimators may be used if abundance information is available.

¹There are exceptions. Methods based on extrapolation of accumulation curves, in particular, might be used to estimate species richness at larger spatial (and temporal) scales than that sampled. There are many scaling considerations to be made that are unique to this type of extrapolation.

Thus, despite the greater effort involved in collecting abundance data, it may be useful to record species abundances so that abundance-based estimators may be used as well.

Other Sampling Issues: Surrogates for Quadrats and Species

Two other sampling issues bear mention here. First, it is important to note that the use of areal units (quadrats) for sampling units is not required. Indeed, although quadrats are often appropriate for plants and other sessile organisms, they are less so for mobile organisms. For mobile taxa, it is useful to substitute a more practical measure—such as observer-hours, trap-days, or volume of substrate—as a sampling unit. Additionally, all is not lost if sampling units are of unequal sizes. Equal-sized samples will meet the assumptions for a larger number of estimators. However, some estimators exist which may be applied when it is not possible to keep sample sizes approximately constant over a census.

Second, techniques for estimating species richness are potentially applicable to taxonomic levels other than species. For any of a variety of reasons, it is often impractical or impossible to key all organisms censused to the species level. For example, in studies of paleontological data, it may only be possible to place an individual to the generic level. In other cases, the presence of undescribed species or other lack of knowledge of species status may necessitate the use of a morphospecies concept. In any case, it is important to note that richness estimators will estimate the number of classes (genera and morphospecies in the previous examples) at whatever taxonomic level was used in sampling.

Estimators Based on Sampling Theory

Species richness estimators are all alike in the obvious way: They all estimate species richness. However, SR estimators take different approaches to estimation. This section presents approaches involving fine-scale, detailed models of the sampling process. *Estimators Based on Extrapolation* discusses extrapolative methods based on coarse-scale, global models of species accumulation.

Models of the Sampling Process: General Concepts

For the fixed collection from which we sample, $(r_0, \dots, r_n)$ specifies the distribution of abundances among the species. Sampling introduces randomness into our data so that when we census the area, we record $(X_0, \dots, X_{S_{\text{obs}}})$ from which we compute $(R_0, \dots, R_N)$. When we sample a set of t quadrats, we may keep track of the abundance of the i th species within the j th quadrat, $X_{i,j}$. Then, we compute the abundance of species i by $X_i = \sum_{j=1}^t X_{i,j}$. However, in many cases, we may be unable to distinguish individuals. In these cases, we record $Y_{i,j}$ from which we compute the incidence of species i by $Y_i = \sum_{j=1}^t Y_{i,j}$. The distribution of $X_{i,j}$ depends on how we sample individuals.

Suppose we sample from a region (an urn) containing n individuals (marbles) distributed among s species (colors). Write x_i for the number of individuals contained in species i . We collect N individuals out of n and S_{obs} species out of s . If we sample with replacement, we find that the number of

observations of species i , written X_i , has probability

$$P\{X_i = a\} = \binom{N}{a} \left(\frac{x_i}{n}\right)^a \left(1 - \frac{x_i}{n}\right)^{N-a} \quad (1)$$

If we sample without replacement

$$P\{X_i = a\} = \frac{\binom{x_i}{a} \binom{n-x_i}{N-a}}{\binom{n}{N}} \quad (2)$$

Under certain conditions, both of these distributions can be approximated by the Poisson distribution according to

$$P\{X_i = a\} = \frac{(N\lambda_i)^a}{a!} e^{-N\lambda_i} \quad (3)$$

where $\lambda_i = x_i/n$. Strictly speaking, the approximation of Eq. (1) is exact only for communities containing infinite species richness and infinite abundance. Practically speaking, the Poisson approximation should work best on large, species-rich communities. A similar argument holds for the approximation of Eq. (2). The requirement that n be considered infinite is sufficient to get to Eq. (3), but it is not necessary. For example, if the successive times between discoveries of an individual of species i are exponentially distributed and the number of individuals found in disjoint samples are independent, then we will get Eq. (3). There is a natural way in which this can happen. First, detections of individuals must be independent events. Second, once we know the current value of X_i , the distribution of future values X_i must be completely determined. Then, we can expect that X_i can be modeled with a Poisson process.

Species Observed (S_{obs})

As a starting point, we consider the number of observed species, S_{obs} , as our first estimate of s . Our presentation of S_{obs} serves as the template for the more complicated estimators to follow. First, we consider the type of data we record. Then, we state the assumptions made in deriving the estimator and its properties. We next turn to theoretical properties of the estimator, for example, its bias and variance. Finally, we discuss issues related to the application of the estimator to real data.

Estimators may be applied to two types of data: species abundance and species incidence. If we record abundance, denoted $X_{i,j}$, our data set will be a matrix of the number of individuals of species i captured on sampling occasion j .

We define the abundance statistics, R_i , to be the number of species containing exactly i individuals. Then,

$$R_i = \sum_{j=1}^s I(X_j = i) \quad (4)$$

We define the incidence statistics, F_i , to be the number of species occurring in exactly i samples in a census. Then,

$$F_i = \sum_{k=1}^s I(Y_k = i) \quad (5)$$

When we wish to refer to the vector of R_i or F_i values for a given data set we will write $\mathbf{R}$ and $\mathbf{F}$, respectively. The number

of species observed in a census S_{obs} may be written in terms of either the abundance or the incidence statistics: $S_{\text{obs}} = \sum_{i=1}^N R_i = \sum_{i=1}^t F_i$. In some cases, we use only the lower order statistics to correct estimator bias. We can visualize the difficulties inherent in estimator design by considering how information accumulates over the R_i . Let the number of species having fewer than k individuals be S_k . Similarly, N_k is the number of individuals representing these S_k species. Therefore,

$$S_k = \sum_{i=1}^k R_i \quad (6)$$

$$N_k = \sum_{i=1}^k iR_i \quad (7)$$

Figure 2 shows a plot of N_k and S_k vs k for real data collected on mist-netted birds. In Figure 3, we plot N_k as a function of S_k . This plot reveals an apparently exponential relationship between N_k and S_k . These figures show that information may be distributed very unevenly in the data set. This means that we shall have few data points (e.g., N_1 and N_2) where we wish to concentrate our estimation effort (S_1 and S_2). This is the worst possible distribution of information if we want to estimate the number of rare species from a simple transformation of the data. For example, an estimator using only $E[N]$ and $E[S]$ will probably do poorly for many real data sets.

Suppose we model sampling in terms of the probability of detection of individuals of each species, $\mathbf{q} = (q_1, \dots, q_s)$, and the number of individuals observed, N . We assume that each individual of a species has the same capture probability

throughout the entire census. Thus,

$$E[S_{\text{obs}} | (q_1, \dots, q_s)] = s - \sum_{i=1}^s (1 - q_i)^N \quad (8)$$

We record the incidence, $Y_{i,j}$, of species i during sample j giving a data matrix whose entries are either 0, for no detection, or 1 when any individuals of i get detected on occasion j . For an entire census, the number of detections of species i is $Y_i = \sum_{j=1}^t Y_{i,j}$. Then we may define $\mathbf{p} = (p_1, \dots, p_s)$ to be the vector of species detection probabilities. After t samples, we compute

$$E[S_{\text{obs}} | (p_1, \dots, p_s)] = s - \sum_{i=1}^s (1 - p_i)^t \quad (9)$$

Equations (8) and (9) show that S_{obs} is biased over finite sampling. In the following, consideration of incidence and abundance versions of S_{obs} parallel on another. Therefore, we focus on the incidence data.

As we increase sample size we have for any i , $\lim_{t \rightarrow \infty} P\{Y_i > 0 | \mathbf{q}\} = 1$. However, in practical terms, we would like to know just how fast S_{obs} gets close to s . Suppose that the p_i are independent and identically distributed (iid) with distribution $H(p)$ and probability density $h(p)$ and consider $E[s - S_{\text{obs}}]/s$. The relative rate of convergence of the mean error is given by this expectation taken over all $\mathbf{p}$:

$$\frac{s - E[S_{\text{obs}}]}{s} = \int_0^1 (1 - p)^t h(p) dp \leq (1 - E[p])^t \quad (10)$$

When we have few rare species, $E[p]$ will be close to 1 and S_{obs}/s will converge quickly to 1. Note that in absolute terms if s is large we may still have many rare, undetected species.

Figure 2 The accumulation of species and individuals with increasing abundance class size for a bird community in southeastern Arizona (W. Leitner, unpublished data). Note that N_k changes relatively slowly where S_k changes quickly and vice versa.

Figure 3 The accumulation of individuals as a function of accumulated incidence for a bird community in southeastern Arizona (W. Leitner, unpublished data). Note that N_k is nearly exponential with S_k . We shall have few data points (e.g., N_1 and N_2) at which we wish to concentrate our estimation effort (S_1 and S_2).

When we have a large proportion of rare species, the convergence will of course be much slower. Now, S_{obs} is a random variable and the variance in S_{obs} is

$$\text{VAR}(S_{\text{obs}}) = s \int_0^1 ((1-p)^t - (1-p)^{2t}) h(p) dp \quad (11)$$

The root mean square error will then decrease approximately like the square root of the error in the mean. Perhaps one of the indices of diversity that measure evenness could be used to sharpen confidence intervals in some way. Before undertaking the design of such a method, it would be beneficial to know if any function of F could be used to increase our confidence in our estimate of $E[S_{\text{obs}}]$. Burnham and Overton (1978) show that $(F_1, \dots, F_t)$ are sufficient for $\mathbf{p}$ under the assumption of iid p_i . Now, the distribution of S_{obs} is determined by the distribution of $\mathbf{p}$ because $S_{\text{obs}} = \sum_{i=1}^t F_i$. Therefore, to increase our confidence in our estimator we should focus directly on reducing its variance. Thus, our goals in estimating SR should include getting estimators that decrease the bias faster than $(1 - E[p])^t$ and whose standard errors decrease faster than $\sqrt{(1 - E[p])^t}$. Often, these goals will conflict with one another. However, knowing that the bias decreases like $(1 - E[p])^t$ tells us that for large enough t , the bias decreases faster than t^{-k} , $k = 1, 2, \dots$. Resampling methods can use this fact to accelerate the rate of bias reduction.

Resampling Methods (S_{jk} , S_b)

We can very rarely expect

$$E[f(X)] = f(E[X]) \quad (12)$$

When $f(x)$ is linear in x then Eq. (12) holds. Suppose that $f(x)$ is nonlinear. Then as x gets spread away from $x = E[X]$ the function f can over- or underweigh the contribution of X to the mean. Thus, both the nature of f and the distribution of X contribute to bias. For this reason, outliers (points far from $E[X]$) can severely alter the approximation $E[f(X)] \approx f(E[X])$. Most estimators derive from just such an approximation. Therefore, when we have outliers, we can sometimes improve our estimate by deleting them from the data set. A version of this approach applied to data not so clearly identified as extreme is the intuitive basis for the jackknife and bootstrap estimators. If the order in which data are recorded does not matter, then we should expect that the relationship between the distribution of t and $t-1$ data points should inform us about the relationship between the distribution of t and $t+1$ data points. Thus, the common property that underlies both techniques is the exchangeability of the data. There are two resampling approaches we consider: jackknifing and bootstrapping. In each case, we describe the resampling strategy that gives rise to the estimator. However, in each case it turns out that actual resampling need not be done. The F statistics contain the same information we would obtain from resampling.

Jackknife Estimator (S_{jk})

Jackknifing involves computing the average value of a statistic on a reduced data set. One removes each combination of k data points in a data set and computes the statistic of interest to give a set of new pseudostatistics. Then, by taking a suitably weighted average of these statistics we get a reduced-bias version of the original statistic. The number of data points removed at a time gives the order of the jackknife. The most obvious statistic to which we can apply the jackknife is the

number of observed species, S_{obs} . As discussed previously, S_{obs} is a biased estimator of s . To apply the jackknife technique to S_{obs} we need three assumptions:

1. The capture probabilities may vary across species,
2. The capture probabilities do not change during the census,
3. The bias in S_{obs} decreases at least as fast as $1/t$.

Under these assumptions, Burnham and Overton (1978) propose a generalized jackknife estimator for species richness, simplified by Smith and Van Belle (1984):

$$S_{jk} = S_{\text{obs}} - \frac{1}{k!} \sum_{j=1}^k F_j \sum_{i=j}^k (-1)^i \binom{k}{i} \frac{\binom{t-j}{i-j}}{\binom{t}{i}} (t-i)^k \quad (13)$$

where k gives the order of the estimator. S_{jk} does not require that we actually do the resampling. To better understand the properties of S_{jk} , we consider how the first-order jackknife estimate of S_{obs} , written S_{j1} , would be produced.

Suppose we compute a statistic, $D(X_1, \dots, X_t) = D_t$ from t observations of X . Now, we want to consider the effect of each observation in turn by removing it from the data set. However, we do not want the order in which we do the removal to matter. Within a given sampling occasion, there may be time of day or other local differences. For example, during bird banding operations we may consistently catch flycatchers later in the day than warblers because it may take time for flying prey to become active. Then, resampling within a trapping occasion may introduce heterogeneity. Thus, we shall conduct jackknife resampling by adding or removing entire quadrats.

Let us remove the i th quadrat and compute D without this quadrat. Call this value $D_{(i)}$. Do this for each i . The mean of these $D_{(i)}$,

$$D_{t-1} = \frac{\sum_{i=1}^t D_{(i)}}{t} \quad (14)$$

gives rise to the first-order jackknife estimate

$$D_{j1} = tD_t - (t-1)D_{t-1} \quad (15)$$

Now, D_{j1} will be less biased than D_t if

$$E[D_t] = s + \sum_{i=1}^{\infty} \frac{b_i}{t^i} \quad (16)$$

where the b_i do not depend on t . If the bias of D_t decreases like $1/t$ —that is, $b_1 \neq 0$ —then the bias in D_{j1} decreases like $1/t^2$.

Suppose $D = S_{\text{obs}}$. If assumption 3 holds, then we can easily get

$$S_{j1} = S_{\text{obs}} + \frac{t-1}{t} F_1 \quad (17)$$

The higher order estimates are considerably more complicated but depend on the assumptions in the same way. As we increase the order of the jackknife, we get greater bias reduction. Unfortunately, we can expect that removing data to reduce bias might increase estimator variance. We see from Eq. (13) that S_{jk} is a linear combination of the F_i with constant coefficients, $a_{i,k}$ given t and k . Burnham and Overton (1978)

give the unconditional variance as

$$\text{VAR}(S_{jk}) = \sum_{i=1}^t a_{i,k}^2 E[F_i] - \frac{E[S_{jk}]^2}{s} \quad (18)$$

Note that as we increase the order from k to $k+1$ the coefficient of F_{k+1} becomes nonzero and therefore increases the variance. Furthermore, a quick check of the lower order coefficients reveals that they also increase with k . Therefore, as we expected, the variance increases with k . Thus, we tradeoff bias reduction against increased noise. Two methods have been proposed for choosing the order of the jackknife. The first method tests the hypothesis that $E[S_{jk} - S_{j,k+1}] = 0$ using the test statistic

$$T_i = \frac{S_{j,k+1} - S_{jk}}{\sqrt{\text{VAR}(S_{j,k+1} - S_{jk} | D)}} \quad (19)$$

If we can reject this hypothesis for $k=1$ then we proceed to test successive values of k until we fail to reject. The difficulty with this test is that quadrat information comes in discontinuous jumps so that the order used in estimation may jump around during the course of a census. Burnham and Overton (1978) suggest an interpolation technique that smoothes this behavior. The power of the jackknife technique is that it requires very little knowledge about the distribution of the data. It is thus nonparametric. An argument like the one presented previously on species observed tells us that assumption 3 is reasonable for finite collections of species. The first two assumptions, however, require biological information. For example, suppose we sample a site containing migratory animals. Then, when we sample determines, to a large extent the distribution of number of individuals observed. If we sample across a productivity gradient then we would not expect the distribution of a given species' abundance, $(X_{1,1}, \dots, X_{1,t})$, to be symmetric. That is, the quadrats would not be exchangeable. This changes the importance of each quadrat on removal, making some have a deterministically larger effect. Consequently, the effective rate of bias reduction may become much smaller than $1/t^2$. Nonetheless, with attention to census design, such issues can be minimized. If in addition we assume that the p_i are iid random variables, then Burnham and Overton (1978) show that F is sufficient for the distribution of the capture histories. This result does not depend on the resampling protocol. This assertion will apply to some of the other estimators we examine.

Bootstrap Estimator (S_B)

Bootstrap estimation begins by constructing a surrogate data set by sampling the original data set with replacement. We shall bootstrap to remove bias in S_{obs} , so we shall once again focus on incidence-based data. Smith and van Belle (1984) analyzed the bootstrapping process to derive

$$S_B = S_{\text{obs}} + \sum_{i=1}^{S_{\text{obs}}} \left(1 - \frac{Y_i}{t}\right)^t \quad (20)$$

Just as in the jackknife estimator, we analyze the resampling process to get the estimate that would result if we actually did the resampling. We would like to think of resampling as a surrogate for doing multiple replicate

censuses. Let $s = \text{bias} + E[S_{\text{obs}}]$. If we knew the bias and $E[S_{\text{obs}}]$ we would be done. To estimate the bias over all possible sampling outcomes, we would need to know the distribution of the X_i . Let S_{obs} play the role of s , and let $(X_1, \dots, X_{S_{\text{obs}}})$ approximate $(x_1, \dots, x_s)$. Then, if we resample the X_i multiple times, we can estimate S_{obs}^* , the mean number of species found in the replicates. Then $\text{bias}_r = S_{\text{obs}} - S_{\text{obs}}^*$ is an estimate of $s - E[S_{\text{obs}}]$, the true bias. Now, we have a single point estimate of $E[S_{\text{obs}}]$, namely, S_{obs} . Therefore, we estimate s by $S_B = S_{\text{obs}} + \text{bias}_r$. We just need to compute bias_r . We assume that

1. Detection probabilities, p_i , may vary between species,
2. The p_i remain fixed during sampling.

Then, on resampling we find that

$$\text{bias}_r = \sum_{i=1}^{S_{\text{obs}}} \left(1 - \frac{Y_i}{t}\right)^t \quad (21)$$

which leads us to Eq. (20).

The variance in S_B given by Smith and Van Belle (1984) is

$$\begin{aligned} \text{VAR}(S_B) &= \sum_{i=1}^{S_{\text{obs}}} \left(1 - \frac{Y_i}{t}\right)^t \left(1 - \left(1 - \frac{Y_i}{t}\right)^t\right) \\ &+ 2 \sum_{i=1}^t \sum_{j=1}^t \left(\left(\frac{Z_{ij}}{t}\right)^t - \left(1 - \frac{Y_i}{t}\right)^t \left(1 - \frac{Y_j}{t}\right)^t \right) \end{aligned} \quad (22)$$

where Z_{ij} are the number of quadrats that jointly lack species i and j . For large t we can replace $(1 - Y_i/t)t$ by e^{-Y_i} . Then, as t gets large the variance in the estimator goes to zero as long as the tendency of species to co-occur decreases sufficiently fast as t increases. Therefore, species that interact strongly, for example, core members of a mixed foraging flock, will tend to inflate estimator variance.

Moment Estimators (α , S_{AM} , S_{IM})

These methods all derive relationships between the moments of various distributions. The moments of a distribution, defined by $E[X^r]$, where r is a positive integer, are used to simplify the analysis. At a minimum, the relationship between various moments reflects assumptions about the sampling process. In other cases, we require special assumptions about the abundance distribution.

Fisher's α

Fisher's α is intermediate between species richness and species diversity. It measures species richness but does so in terms of the parameters of the abundance distribution and the sampling process. It is a parametric estimator of richness when applied as described later. Unfortunately, α involves some rather technical arguments. This has led to two different ways to define α . The first follows from Fisher's use of the gamma distribution to model the abundance distribution. The second results from a limit taken on the functional relationship between the mean sample size and the mean number of observed species in a sample. As we shall see, properties that are exact for one definition of α are approximations for the other. We shall focus on two key properties of α : (i) sample size

dependence of α and (ii) estimating species richness from α . We begin by defining α , as Fisher did, in terms of the sampling process and the abundance distribution under study. Then, we derive the second version of α from the first by considering what happens when the distribution under study represents an arbitrarily large number of species. Finally, we consider the practical problem of calculating and interpreting α when we know very little about the true nature of the abundance distribution.

Derivation of α

Fisher's α was first introduced (Fisher *et al.*, 1943) as a means for estimating the parameters of empirical abundance distributions that had a negative binomial shape. Fisher made three key technical assumptions in his derivation of α that show up in its properties. First, Fisher assumed that the sample was drawn from a community of infinitely many individuals. As we shall see, this allowed Fisher to use the Poisson process to model the sampling of individuals. Second, he assumed that the community was composed of species whose mean abundances were distributed according to a gamma distribution. Finally, Fisher considered the limiting case of a community containing an infinite number of species.

If we assume that the order in which we discover species is unimportant (*i.e.*, individuals are exchangeable) then $P\{N_1 = x\}$ specifies the probability that we observe a species represented by x individuals. With $P\{N_1 = x\}$ we can compute $E[S_{\text{obs}}]$ and $E[N]$ because

$$E[S_{\text{obs}}] = s \sum_{x=0}^n P\{N_1 = x\} \quad (23)$$

$$E[N] = s \sum_{x=0}^n x P\{N_1 = x\} \quad (24)$$

Fisher begins with the assumption that $P\{N_i = x | m_i\} = (m_i^x / x!) e^{-m_i}$, where m_i is the number of individuals of species i expected in the sample. The number of individuals in a sample, N , or the sample size, is usually a random variable because trapping and other forms of detection are random processes. Suppose that detection is a Poisson process, or very nearly so, and that our sampling region has extent A . Then, we expect that $m_i/A = \lambda_i$ where λ_i is the density of species i .

Fisher's second assumption was that the λ_i possess the gamma distribution with parameters $1/p$ and k . The density of a gamma random variable, $f(\lambda, p, k)$, is given by

$$f(\lambda, p, k) = \frac{1}{\Gamma(k)} \frac{1}{p} \left(\frac{\lambda}{p}\right)^{k-1} e^{-\lambda/p}$$

where $\Gamma(k) = \int_0^\infty x^{k-1} e^{-x} dx$. The gamma distribution has three features which made it an obvious first choice. First, gamma random variables must be nonnegative just like species' densities. Second, the gamma distribution can take on a wide range of shapes. Lastly, computations using the gamma distribution are often tractable. To spread out densities evenly over a community, k must be close to zero.

Suppose we sample a region by censusing areas of increasing size. The larger areas should contain more

individuals. Let $\mu_A = E[N|A, s]$ and $v_A = E[S_{\text{obs}}|A, s]$ give the expected number of individuals and species, respectively, in a sample of size A drawn from a community containing s species. Then,

$$P\{N = x|A, s\} = \int_0^\infty \frac{(\lambda A)^x}{x!} e^{-\lambda A} f(\lambda) d\lambda \quad (25)$$

$$= (1 + pA)^{-k} \frac{\Gamma(x+k)}{\Gamma(k)x!} \left(\frac{pA}{1+pA} \right)^x \quad (26)$$

Using Eq. (26) in Eqs. (23) and (24) it can be shown that

$$v_A = s(1 - (1 + pA)^{-k}) \quad (27)$$

$$\mu_A = skpA \quad (28)$$

Now, if the relative abundance of species is the same at all sampling scales it must be that the distribution's shape and thus k are fixed. Although we expect smaller sample sizes in smaller A , the number of species from which we sample remains fixed at s . This means that μ_A can only change as a function because of A or p . Therefore, we collect all the constants from Eq. (28) into α and write $\mu_A = \alpha pA$ and set $\alpha = sk$. This is Fisher's definition of α (with the effect of sampling extent made explicit). When defined this way, α depends on only the shape of the distribution and not on the expected sample size. Using this definition for α , we can rearrange Eq. (27) and substitute Eq. (28) to get

$$\left(1 - \frac{v_A}{s}\right)^{-s\alpha} = 1 + \frac{\mu_A}{\alpha} \quad (29)$$

Equation (29) defines μ_A as a function of v_A with parameters α and s . In fact, Eq. (27) is a species-area relationship. At $A = 0$ we expect no species and for $A \rightarrow \infty$ we expect s species. A little calculus shows that

$$\frac{dv_A}{d\ln(A)} = \frac{\alpha}{1 + \frac{\alpha}{\mu_A}} \frac{s - v_A}{s} \quad (30)$$

Consequently, if we plot $\ln(s - v_A)$ vs $\ln(A)$ we get a line of slope $(\alpha/s)(1/(1 + (\alpha/\mu_A)))$. Now, μ_A quickly exceeds α in many cases at very small areas. Thus, for most sample sizes we have constant slope α/s . Therefore, we may estimate s if we know α . Unfortunately, this will give only a lower bound on s because the sensitivity of the slope to changes in s decreases as s increases. Nonetheless, we need a method for estimating α that does not involve s . To do this, we will want to consider communities that contain many species. Again, calculus tells us that if we let $s \rightarrow \infty$ in Eq. (29) we get

$$e^{-v_A/\alpha} = 1 + \frac{\mu_A}{\alpha} \quad (31)$$

The solution to Eq. (29) gives us the second way of defining α . In order to avoid confusion, we write α^* for the solution of Eq. (31). We do not need to assume anything about the sampling procedure or the abundance distribution, except that μ_A and v_A exist, in order to compute α^* . Note that $\alpha \rightarrow \alpha^*$ as $s \rightarrow \infty$. Unlike α , α^* may depend on sample size. This can be seen

from

$$\frac{\partial \alpha}{\partial A} = \frac{-\alpha^2}{\mu_A v_A + \alpha^* v_A - \alpha^* \mu_A} \left(\frac{\partial \mu_A}{\partial A} - \frac{\mu_A + \alpha^*}{\alpha^*} \frac{\partial v_A}{\partial A} \right) \quad (32)$$

because, in general,

$$\frac{\partial \mu_A}{\partial A} - \frac{\mu_A + \alpha^*}{\alpha^*} \frac{\partial v_A}{\partial A} \neq 0 \quad (33)$$

If we apply the assumptions Fisher made about sampling from a gamma abundance distribution, then

$$\begin{aligned} \frac{\partial \mu_A}{\partial A} - \frac{\mu_A + \alpha^*}{\alpha^*} \frac{\partial v_A}{\partial A} &= p\alpha \\ \left(1 - \frac{\alpha(\mu_A + \alpha^*)}{\alpha^*(\mu_A + \alpha)} \left(1 + \frac{\mu_A}{\alpha}\right)^{-\alpha/s}\right) &\rightarrow 0 \text{ as } s \rightarrow \infty \end{aligned} \quad (34)$$

Therefore, the independence of α from A carries over to α^* , once again, in the limit of large s . Most often, however, computations of α do not in fact use v_A or μ_A . Rather than average values, the raw numbers of species and individuals observed serve as estimates of the respective expectations. This leads to $\hat{\alpha}$ an estimate of α^* :

$$N = \hat{\alpha}(1 - e^{-S_{\text{obs}}/\hat{\alpha}}) \quad (35)$$

Unfortunately, Eq. (35) cannot be solved directly for $\hat{\alpha}$ in terms of S_{obs} and N .

We can get an approximate solution to Eq. (35) by expanding the function $\hat{\alpha}(N, S_{\text{obs}})$ about the point (μ_A, v_A) in a second-order Taylor series using the fact that $\hat{\alpha}(\mu_A, v_A) = \alpha$. Then, we find the bias is approximately

$$\begin{aligned} E[\hat{\alpha}(N, S_{\text{obs}}) - \alpha] &\approx \frac{\alpha^2(\mu_A + \alpha)}{(\mu_A v_A + \alpha v_A - \alpha \mu_A)^3} \\ (v_A^2 \text{VAR}(N) + \mu_A^2 \text{VAR}(S_{\text{obs}}) - \mu_A v_A \text{COV}(N, S_{\text{obs}})) &\quad (36) \end{aligned}$$

and the sample variance of $\hat{\alpha}$ is

$$\begin{aligned} \text{VAR}(\hat{\alpha}) &\approx \frac{\alpha^4}{(\mu_A v_A + \alpha v_A - \alpha \mu_A)^2} \\ &\left(\text{VAR}(N) + \left(\frac{\mu_A + \alpha}{\alpha}\right)^2 (\text{VAR}(S_{\text{obs}}) + 2\text{COV}(N, S_{\text{obs}})) \right) \end{aligned} \quad (37)$$

To this point, we have needed no information regarding abundance distributions or sampling methods. Therefore, any conclusions we can draw from Eqs. (36) and (37) apply to any study system. Let $\gamma(X)$ be the coefficient of variation of X . Then, even for moderate sample sizes,

$$\begin{aligned} E[\hat{\alpha}(N, S) - \alpha] &\approx \frac{\alpha^2}{v_A} (\gamma(N)^2 + \gamma(s)^2 \\ &- \gamma(N)\gamma(S_{\text{obs}})\text{CORR}(N, S_{\text{obs}})) \end{aligned} \quad (38)$$

For moderate A the sampling process will be nearly Poisson. Therefore, N will be Poisson because it is a sum of Poissons. Thus, $\gamma(N)$ will decline with sample size. As we increase sampling effort, A , it must be that v_A is nondecreasing because we cannot

undiscover species. For most collections, the probability of finding new species decreases as we increase sampling effort because we generally find common species first and rare species after prolonged sampling. Thus, $\gamma(S_{\text{obs}})$ must also decline with increases in A . From $-1 \leq \text{CORR}(N, S_{\text{obs}}) \leq 1$ we can see that bias decreases as fast as α^2/v_A . This means that $\hat{a}$ should depend weakly on sample size. Once a sample large enough to get good estimates of the various coefficients of variation has been gathered, $\hat{a}$ will show little further change. This holds for any abundance distribution for which the variances and means of N and S_{obs} exist. The fluctuations of $\hat{a}$ can be seen from Eq. (37) to decrease as α/v_A as well so that $\hat{a}$ closely approximates α^* for large A . However, we should remember that α expresses a relationship between the means of N and S_{obs} . Therefore, we will need more information on the abundance distribution if we are to interpret the number of undiscovered species remaining in terms of remaining in terms of $\hat{a}$.

Chao's Abundance-Based Estimator (S_{AM})

Abundance-based methods apply to data sets in which individuals can be readily identified and counted. From our data we compute the statistics $(R_1, \dots, R_N)$ and seek an estimate of $E[R_0]$, the expected number of unobserved species. Chao (1984) proposed

$$S_{\text{AM}} = S_{\text{obs}} + \frac{R_1^2}{2R_2} \quad (39)$$

as a lower bound for s in the limit of infinite sample size.

S_{AM} makes the following two assumptions:

1. Capture probabilities, q_j , may vary among species
2. Capture probabilities remain fixed during sampling

where q_j gives the probability of capture of an individual of species j . The starting point for the derivation of S_{AM} begins with a model of the sampling process.

Using the Poisson approximation as described previously, we get

$$E[R_i] \approx \sum_{j=1}^s \frac{(Nq_j)^i}{i!} e^{-Nq_j} \quad (40)$$

From Eq. (40) we see that this approximation works best when i is small relative to N and q_j is small. Thus, this method should perform best when applied to collections that have relatively few common or abundant species but many rare species. The exponential form of the Poisson approximation permitted Chao (1984) to do some clever analysis using a judiciously chosen distribution function, $F_{\text{AM}}(x)$. The key consequence of the Poisson approximation is that the i th moment of $F_{\text{AM}}(x)$, written μ_i , can be used to estimate $E[R_{i+1}]$ because

$$\mu_i \approx (i+1)! \frac{E[R_{i+1}]}{E[R_1]}. \quad (41)$$

Next, Chao (1984) connects the seen with the unseen species through

$$E[R_0] \approx E[R_1] \int_0^N \frac{1}{x} F_{\text{AM}}(dx) \quad (42)$$

Once again, we have used the Poisson approximation to estimate the expected number of species. This integral

representation reveals two pathways to further analysis: approximate the integrator or approximate the integrand. Chao (1984) approximated the integrator rather than the integrand. By constructing a suitable distribution function that possesses the same first and second moments as $F_{\text{AM}}(x)$, Chao shows that the smallest value taken by Eq. (42) must be $E[R_1]/\mu_1$. Using Eq. (41) and taking the R_i as estimates of $E[R_i]$, we find

$$S_{\text{AM}} = S_{\text{obs}} + \frac{R_1^2}{2R_2} \quad (43)$$

The derivation incorporates the following assumptions into S_{AM} :

1. Sampling is a Poisson process,
2. Third-order and higher moments of F_{AM} may be neglected,
3. The R_i are good estimates of $E[R_i]$

These assumptions determine the statistical properties of S_{AM} . The first assumption could be used to get the sufficiency of $(R_0, \dots, R_N)$ if the q_i were iid random variables with distribution $H(q)$. Then,

$$P(r_0, \dots, r_N) = \binom{s}{r_0, \dots, r_N} \prod_{i=0}^N [\theta_i(H)]^{r_i} \quad (44)$$

where $\theta_i(H) = \int_0^1 \binom{N}{i} q^i (1-q)^{N-i} h(q)$. Paralleling Burnham and Overton (1978), Eq. (44) can be rewritten to permit use of a factorization theorem to assert the sufficiency. If we relax the assumption that the q_i be identically distributed, then we need a model for selecting $H_i(q)$, the distribution function for q_i . For example, if the H_i corresponded to habitat heterogeneity, then the sufficient statistics would presumably incorporate information on variation in habitat type during sampling. The first and the last assumptions allow us to avoid assuming a form for the abundance distribution. S_{AM} is therefore nonparametric. Assumption 2 makes S_{AM} a lower bound for s that increases as sample size increases, indicating that S_{AM} is a biased estimator. Assuming that we have a large enough sample size, we expand the function S_{AM} as a first-order Taylor polynomial about $E[S_{\text{obs}}]$, $E[R_1]$, and $E[R_2]$. Then we can use

$$\begin{aligned} \text{VAR}(aX + bY) &= a^2 \text{VAR}(X) + b^2 \text{VAR}(Y) \\ &\quad + 2ab \text{COV}(X, Y) \end{aligned} \quad (45)$$

to estimate the variance. Working through the analysis and assuming the covariance terms are small gives

$$\begin{aligned} \text{VAR}(S_{\text{AM}}) &\approx \left(1 + \frac{R_1}{R_2}\right)^2 \text{VAR}(R_1) \\ &\quad + \left(1 - \frac{R_1^2}{2R_2^2}\right)^2 \text{VAR}(R_2) + \sum_{i=3}^N \text{VAR}(R_i) \end{aligned} \quad (46)$$

Even when we have the abundance distribution, the indicated variances can be challenging to compute. Chao (1984) used bootstrapping techniques coupled with simulations and tests on well-characterized data sets to evaluate the performance of the S_{AM} . When applied to data sets with known s , S_{AM}

generally had smaller bias and narrower confidence intervals than S_{J1} or S_{J2} .

Chao's Incidence-Based Estimator (S_{IM})

Incidence-based methods apply to data sets in which individuals are not readily identified or counted. We compute $(F_1, \dots, F_N)$ from the data matrix $X_{i,j}$ and seek an estimate of $E[F_0]$, the expected number of unobserved species. Chao (1987) used the same approach as used for S_{AM} to derive

$$S_{IM} = S_{obs} + \frac{F_1^2}{2F_2} \quad (47)$$

for data sets of species incidence. Like the jackknife estimator, the original application of this method was to estimate population sizes. It produces a lower bound for s . The starting point for the derivation of S_{IM} begins as S_{AM} did with a model of the sampling process. Let p_i be the probability of detection of species i . In this case, sampling is as in the jackknife estimator. Therefore, we assume

1. Detection probabilities, p_i , may vary between species.
2. The p_i remain fixed during sampling.
3. The p_i are iid random variables with distribution $H(p)$.

As we saw for S_{JK} , if these assumptions are met then

$$(F_0, \dots, F_t)$$

will be sufficient for H . The last assumption allows us to write

$$E[F_i] = \int_0^1 \binom{t}{i} p^i (1-p)^{t-i} h(p) dp \quad (48)$$

From here we can once again use the Poisson approximation to simplify Eq. (48). In this case, the focus on data sets that concentrate probability over F_1 and F_2 is less critical. The Poisson approximation will still work well if the probability of large p_i is small. From here, Chao (1987) parallels the derivation of S_{AM} using an absolutely continuous version of $F_{AM}(x)$. This distribution function, $F_{IM}(x)$ has moments that satisfy

$$\mu_i \approx (i+1)! \frac{E[F_{i+1}]}{E[F_1]} \quad (49)$$

An integral relationship between F_0 and F_1 analogous to Eq. (42) once again leads us to approximate either integrand or integrator. While S_{IM} arises from approximating the integrator as before, we gain some insight into the relationship between S_{JK} and S_{IM} by considering the other alternative first. If we approximate the integrand, $1/x$, with a k th order polynomial then we find

$$E[F_0] \approx \sum_{i=1}^k (-1)^{i+1} \binom{k}{i} E[F_i] \quad (50)$$

Now, the bias should decrease as the expected number of undiscovered species decreases. This expectation, given by

$$E[F_0] = \int_0^1 (1-p)^t h(p) dp \quad (51)$$

must decrease at least as fast as $1/t$ because $(1-p)^t \leq e^{-tp}$ for $0 \leq p \leq 1$. Equation (50) has, as Chao (1984) points out, the

same form of the k th-order jackknife estimator. The connection between S_{JK} and S_{IM} reflects the assumption made in any jackknife estimator that the bias can be expressed as a power series in $1/t$. Chao (1987) obtains S_{IM} by approximating the integrator rather than the integrand. Then, using an analog to Eq. (41) and taking the F_i as estimates of $E[F_i]$, Chao proposes

$$S_{IM} = S_{obs} + \frac{F_1^2}{2F_2} \quad (52)$$

As with S_{AM} , we have several assumptions built into the derivation of S_{IM} :

1. The p_i are small enough to justify the Poisson approximation to the binomial probabilities of Eq. (48).
2. Third-order and higher moments of F may be neglected.
3. The F_i are good estimates of $E[F_i]$.

First, we note that S_{IM} is nonparametric. Assumption 2 makes S_{IM} a lower bound for s that increases as sample size increases, indicating that S_{IM} is a biased estimator. Chao (1987) estimates the variance of S_{IM} as

$$\text{VAR}(S_{IM}) = \frac{F_2}{4} \left(\left(\frac{F_1}{F_2} \right)^4 + 4 \left(\frac{F_1}{F_2} \right)^3 + 2 \left(\frac{F_1}{F_2} \right)^2 \right) \quad (53)$$

Equation (53) can be used to get approximate confidence intervals for S_{IM} provided that $p_i t$ is not too large. As we increase t , we expect the lower order $F_i \rightarrow 0$ if we are sampling a finite collection of individuals. This would seem to imply that the variance goes to zero with increasing t . However, large t means large $p_i t$ and so makes Eq. (53) a poor approximation. Chao (1987) used real data sets with known s to evaluate S_{IM} , finding that it performed well relative to S_{JK} . For low t , S_{IM} displayed smaller standard error and less negative bias than S_{J2} . However, as t was increased, S_{JK} outperformed S_{IM} . Notably, the data sets tended to have more recaptures with increasing t . Chazdon *et al.* (1998) found similar results.

Estimates Derived from Sample Coverage (S_{AC} , S_{IC})

Sampling of a finite community must eventually capture each individual multiple times. Thus, we can expect that exhaustive sampling would lead to $F_i = 0$ and $R_i = 0$ for the lower order i . An alternative that measures representation of species in the data set while retaining analytic tractability is sample coverage. The sample coverage, C , is defined by

$$C = \sum_{i=1}^s q_i I(X_i > 0) \text{ for abundance data or}$$

$$C = \sum_{i=1}^s p_i I(Y_i > 0) \text{ for incidence data}$$

Chao's Abundance-Based Coverage Estimator (S_{AC})

Chao and Lee (1992) propose a nonparametric estimate of s using estimates of $E[S_{obs}]$, $E[C]$, and $\gamma(q)$. They define the abundance coverage-based estimator S_{AC} as follows:

$$S_{AC} = \frac{E[S_{obs}]}{E[C]} + \frac{E[R_1]}{E[C]} \gamma(q)^2 \quad (54)$$

Intuitively, we see that S_{obs} is inflated by C to adjust for the fraction of the distribution left uncovered. Additional bias correction reflecting the shape of the distribution comes through R_1 and the γ of the distribution. Thus, we are using information from more than just the lower order abundances and may expect S_{AC} to perform better than S_{AM} and S_{IM} when higher order abundances support significant probability. We start with the same two basic assumptions that apply to S_{AM} :

1. Individual detection probabilities, q_i , may vary between species.
2. The q_i remain fixed during sampling.

Thus, the q_i can be regarded as a sequence of random variables with mean $\bar{q}$, variance σ_q , and coefficient of variation $\gamma(q)$.

Then, we find that

$$E[S_{\text{obs}}] = s - \sum_{i=1}^s (1 - q_i)^N$$

$$E[C] = 1 - \frac{\sum_{i=1}^s (1 - q_i)^N}{\sum_{i=1}^s q_i}$$

Of course, if we knew the true values of the q_i we could compute s directly. Instead, we get estimates of $E[S_{\text{obs}}]$ and $E[C]$ from our data. Now, $E[S_{\text{obs}}]$ and $E[C]$ are functions of s and the q_i . Therefore, we would like to eliminate the dependence on the q_i in order to estimate s . If our estimates of $E[S_{\text{obs}}]$ and $E[C]$ are close to the truth, we can use Taylor's theorem to expand about the point $(q_1, \dots, q_s)$ to get

$$s \approx \frac{E[S_{\text{obs}}]}{E[C]} + \frac{E[R_1]}{E[C]} \gamma(q)^2 \quad (55)$$

Now, all we need are estimates of the expectations and the coefficient of variation for the abundance distribution. [Chao and Lee \(1992\)](#) suggest

$$E[S_{\text{obs}}] \approx S_{\text{obs}} \quad (56)$$

$$E[R_1] \approx R_1 \quad (57)$$

$$E[C] \approx \hat{C} = 1 - \frac{R_1}{N} \quad (58)$$

for the various expectations. The coefficient of variation is somewhat more complicated. First, it must always be positive. Second, when the true γ is large, we can expect to need more data to estimate it. It can be easily shown that

$$\gamma^2 = \frac{1}{s} \frac{\sum_{i=1}^s q_i^2}{\bar{q}^2} - 1 \quad (59)$$

and

$$E \left[\sum_{i=1}^N i(i-1)R_i \right] = n(n-1) \sum_{i=1}^s q_i^2. \quad (60)$$

[Chao and Lee \(1992\)](#) then suggest that

$$\hat{\gamma}^2 = \max \left\{ \hat{N}_0 \frac{\sum_{i=1}^N i(i-1)R_i}{(\sum_{i=1}^N iR_i)^2} - 1, 0 \right\} \quad (61)$$

where $\hat{N}_0 = S_{\text{obs}}/\hat{C}$ when $\hat{\gamma}^2 \leq 0.5$. Then we have

$$S_{\text{AC}} = \frac{S_{\text{obs}}}{\hat{C}} + \frac{R_1}{\hat{C}} \hat{\gamma}^2 \quad (62)$$

In Eq. (61) the term $\hat{N}_0$ is an initial estimate of s . If $\hat{\gamma}^2 > 0.5$ the bias can be reduced by using S_{AC} in place of $S_{\text{obs}}/\hat{C}$ to yield

$$\tilde{\gamma}^2 = \max \left\{ S_{\text{AC}} \frac{\sum_{i=1}^N i(i-1)R_i}{(\sum_{i=1}^N iR_i)^2} - 1, 0 \right\} \quad (63)$$

Then, for larger γ we have

$$\tilde{S}_{\text{AC}} = \frac{S_{\text{obs}}}{\hat{C}} + \frac{R_1}{\hat{C}} \tilde{\gamma}^2 \quad (64)$$

It turns out that $S_{\text{obs}}/\hat{C}$ is biased low when the q_i differ from one another (when sample sizes are large enough to permit estimation $\gamma(q)$). Thus, S_{AC} should be biased low. The variance of S_{AC} is approximately a linear combination of $\text{COV}(R_i, R_j)$. It can be shown that

$$\text{VAR}(R_i) = E[R_i] \left(1 - \frac{E[R_i]}{s} \right) \quad (65)$$

$$\text{COV}(R_i, R_j) = -\frac{E[R_i]E[R_j]}{s} \quad (66)$$

Now $R_i \leq s$ so the variance is bounded and decreases with increasing richness. However, for a fixed s , variance depends on how the R_i spread out as we increase t . This in turn depends on the sampling model we use. Here, we have assumed that the q_i remain fixed so that we sample with replacement. Therefore,

$$E[R_i] = \sum_{j=1}^s \binom{N}{i} p_j^i (1 - p_j)^{N-i} \quad (67)$$

Evidently, as N increases, $R_i \rightarrow 0$ with probability 1. Now, the R_i represent N different abundance classes. However, we have only s species. Therefore, the probability that $R_i > 0$ will be spread out over an increasing set of the R_i as N increases. Thus, $E[R_i]$ should become small relative to s as N increases. The simulations performed by [Chao and Lee \(1992\)](#) indicate that at high sample coverage S_{AC} is nearly unbiased. However, [Colwell and Coddington \(1994\)](#) found that S_{AC} tends to overestimate s when sample sizes are small. The difficulty appears to occur for large values of γ . In this case, many of the individuals in a sample represent common species, so there are a few dominant q_i in the collection. In this case, $\hat{C}$ is a poor estimate of sample coverage. However, we can easily ascertain the number of common species in a collection. [Chao et al. \(1993\)](#) suggest truncation of the data set to species with k or fewer representatives. The new estimates for $E[C]$ and $E[S_{\text{obs}}]$

that result are

$$S_{\text{obs},k} = \sum_{i=1}^k R_i \quad (68)$$

$$\hat{C}_k = 1 - \frac{R_1}{\sum_{i=1}^k iR_i} \quad (69)$$

Similarly, we have

$$\hat{\gamma}_k = \max \left\{ \frac{S_{\text{obs},k}}{\hat{C}_k} \frac{\sum_{i=1}^k i(i-1)R_i}{(\sum_{i=1}^k iR_i)^2} - 1, 0 \right\} \quad (70)$$

so that

$$S_{\text{ACk}} = S_{\text{obs}} - S_{\text{obs},k} + \frac{S_{\text{obs},k}}{\hat{C}_k} + \frac{R_1}{\hat{C}_k} \hat{\gamma}_k^2 \quad (71)$$

Chao's Incidence-Based Coverage Estimator (S_{IC})

The incidence-based coverage estimator, S_{IC} , applies to data sets that have the quadrat structure outlined for S_{IM} . Briefly, when we have the presence/absence of data then incidence-based estimators apply. Lee and Chao (1994) found ways to relax many of the assumptions present in S_{AM} , S_{IM} , S_{JK} and S_{AC} . They follow Pollock (1976) by partitioning variability into between-species, within-species, and temporal components. The results involve more complex notation and more complicated proofs but use the same conceptual framework as S_{AC} . For brevity, we present only the case of unequal detection probabilities among species. The estimator for incidence-based coverage is

$$S_{\text{IC}} = \frac{E[S_{\text{obs}}]}{E[C]} + \frac{E[F_1]}{E[C]} \gamma(p)^2 \quad (72)$$

We define p_i as the probability of detection of species i . For S_{IC} we assume that

1. Detection probabilities, p_i , may vary between species.
2. The p_i remain fixed during sampling.

Thus, the p_i can be regarded as a sequence of random variables with mean $\bar{p}$, variance σ_p , and coefficient of variation $\gamma(p)$.

Then, we find that

$$E[S_{\text{obs}}] = s - \sum_{i=1}^s (1 - p_i)^t$$

$$E[C] = 1 - \frac{\sum_{i=1}^s (1 - p_i)^t}{\sum_{i=1}^s p_i}$$

$E[D]$ and $E[C]$ are functions of s and the p_i . Therefore, we would like to eliminate the dependence on the p_i in order to estimate s . We can use Taylor's theorem to expand about the point $(p_1, \dots, p_s)$ to get

$$s \approx \frac{E[S_{\text{obs}}]}{E[C]} + \frac{E[F_1]}{E[C]} \gamma(p)^2 \quad (73)$$

Using the approximations

$$E[S_{\text{obs}}] \approx S_{\text{obs}} \quad (74)$$

$$E[F_1] \approx F_1 \quad (75)$$

$$\hat{C} = 1 - \frac{F_1}{\sum_{i=1}^t iF_i} \quad (76)$$

$$\hat{C} = 1 - \frac{(t-1)F_1 - 2F_2}{(t-1)\sum_{i=1}^t iF_i} \quad (77)$$

and

$$\hat{\gamma}_2 = \max \left\{ \hat{N}_0 \frac{\sum_{i=1}^t i(i-1)F_i}{(\sum_{i=1}^t iF_i)^2} - 1, 0 \right\} \quad (78)$$

where $\hat{N}_0 = S_{\text{obs}}/\hat{C}$ when $\hat{\gamma}^2 \leq 0.5$, we get

$$S_{\text{IC}} = \frac{S_{\text{obs}}}{\hat{C}} + \frac{F_1}{\hat{C}} \hat{\gamma}^2 \quad (79)$$

If $\hat{\gamma}^2$ is large, the bias can be reduced by using S_{IC} in place of $S_{\text{obs}}/\hat{C}$ to compute $\hat{\gamma}^2$. Then, using $\tilde{C}$ for $\hat{C}$, we have

$$\hat{S}_{\text{IC}} = \frac{S_{\text{obs}}}{\tilde{C}} + \frac{F_1}{\tilde{C}} \hat{\gamma}^2 \quad (80)$$

As $\hat{C}$ increases, the bias must decrease. Therefore, we can expect that the assumptions of fixed p_i will lead to S_{IC} underestimating s in most cases. The variance of S_{AC} is approximately a linear combination of $\text{COV}(F_i, F_j)$. It can be shown that

$$\text{VAR}(F_i) = E[F_i] \left(1 - \frac{E[F_i]}{s} \right) \quad (81)$$

$$\text{COV}(F_i, F_j) = -\frac{E[F_i]E[F_j]}{s} \quad (82)$$

The variance is thus bounded and decreases with increasing richness because $F_i \leq s$. Now, as we increase t each of the species will be detected a different number of times with probability 1 (even if they have the same p_i). Therefore, there will be at most s nonzero F_i among $(F_1, \dots, F_t)$. Thus, $E[F_i] \rightarrow 0$ as $t \rightarrow \infty$. As with S_{AC} , the effects of a few dominant p_i can be adjusted for using the methods of Chao *et al.* (1993). If we truncate the data set to species with k or fewer representatives. The new estimates for $E[C]$ and $E[D]$ that result are

$$S_{\text{obs},k} = \sum_{i=1}^k F_i \quad (83)$$

$$\hat{C}_k = 1 - \frac{F_1}{\sum_{i=1}^k iF_i} \quad (84)$$

Similarly, we have

$$\hat{\gamma}_k^2 = \max \left\{ \frac{S_{\text{obs},k}}{\hat{C}_k} \frac{\sum_{i=1}^k i(i-1)F_i}{(\sum_{i=1}^k iF_i)^2} - 1, 0 \right\} \quad (85)$$

so that

$$S_{ICk} = S_{obs} - S_{obs,k} + \frac{S_{obs,k}}{\hat{C}_k} + \frac{F_1}{\hat{C}_k} \hat{\gamma}_k^2 \quad (86)$$

Estimation on Heterogeneous Samples

Increasing sample size often improves estimator performance through the operation of the laws of large numbers. We get better estimates because the means of many summary statistics become closer to the truth and the variation in these estimates decreases with increasing sample size. Of course, increasing sample sizes increases the cost of performing the census. However, a potentially more serious problem accompanies increases in sample size. In most cases, larger samples take more time or cover larger areas. Inevitably, this means increasing heterogeneity in the sampling process. For example, seasonal variation or habitat heterogeneity will cause detection probabilities to change within a species as sampling progresses. A similar problem occurs in estimating the population size of a single species. Pollock *et al.* (1984) and Lee and Chao (1994) modeled the contribution of heterogeneity in individual capture probabilities to population size estimates. Just as most of the estimators presented so far have been adapted from population size estimators, Nichols *et al.* (1998) applied Pollock's robust estimation method to species richness estimation. These methods incorporate many parameters to characterize the effect of heterogeneity on capture probabilities. Consequently, the estimators are substantially more complicated. Although we may better adjust an estimator to the needs of a given census, the added complexity tends to obscure the overall relationship between sample size and species richness.

Estimators Based on Extrapolation

In order to approximate exhaustive sampling or to elucidate large-scale patterns, many studies extrapolate beyond the extent of a given census. These studies focus less on the sampling process and more on biological processes that operate over scales that are too large to survey in detail. As noted previously, studies that increase the scope of sampling usually encounter a wider range of heterogeneity. Heterogeneity increases due to the responses of individual species to the range of environmental and biological conditions as we increase the study area or the time span of the sample. As we increase sample size, we expect that the correlation in the abundance of arbitrarily selected species should decrease. This decreasing correlation permits us to average over the fine-scale, detailed distribution of the components of S_{obs} and focus on the coarse-scale, global behavior of S_{obs} . When most species in large communities interact weakly with most other species, our experience with the laws of large numbers suggests that there should be a trend relating species richness to area or time span. If the interactions are weak enough relative to sample size, the distribution of fluctuations about the trend may display regular, perhaps even Gaussian, behavior. Our models of species accumulation can then be built with two pieces of

information. First, we shall need the average rate of increase in richness as a function of sample size. Second, we need the variability about the mean. The first piece gives us a trend we can extrapolate. The second allows us to fit the model to the data. Most extrapolation methods focus on the trend model and assume a form for the noise that makes curve fitting convenient.

Once we have a suitable model, we can then extrapolate beyond the areas in which we actually sample. We must keep in mind that this extension confounds the contribution of ecological process and sampling effort to diversity. At smaller scales, sampling effort dominates the accumulation of diversity. However, at larger scales, we encounter heterogeneity effects that may scale differently than the effects of sampling effort. Often, we have no general guidelines for selecting one of the several functional forms for species accumulation. Most of the difficulty in applying these models stems from fitting the nonlinear models to data. For brevity, we omit the technical details of curve fitting. We briefly consider a few representative forms here. These are species–area curves, birth chains, and the Michaelis–Menten equation.

To evaluate extrapolation models, we need at least three pieces of information. First, is the trend nondecreasing? Even though it may seem counterintuitive, there are models whose rate of species accumulation increases at small sample sizes (Leitner and Rosenzweig, 1997; Soberón and Llorente, 1993). Second, does the trend have an asymptote? Third, what curvature does the functional form of the model predict? The fitting of the model to data depends on the overall shape of the function. Less obviously, the model transforms the noise that gives rise to the residuals used to evaluate the goodness of fit.

Species–Area Curves

Species–area curves may use samples from disjoint areas or nested areas. This approach has a long history due primarily to its flexibility. There are several functions that may be fit to the data in order to extrapolate to a large area. Chief among these are $\log(S_{obs})$ vs $\log(N)$ and S_{obs} vs $\log(N)$. Note that these curves have no asymptote. Furthermore, their curvature is often too shallow to give the best fits to the data. The key parameters of interest are the slope (the z -value) and intercept of the plot. The slope in particular has drawn much attention in both theoretical and applied circles. Given the abundance distribution, one may use methods similar to Fisher's approach in deriving z to make theoretical predictions about the magnitude of the slope. Preston (1962) and May (1975) both claim theoretical predictions for z -values built solely on the assumption of the lognormal distribution abundances. This work implied that the species–area curve, at least for lognormal distributions, reflected nothing more than sampling. However, this conclusion rests on the tacit assumption that the abundance distribution be lognormal at all scales. This assumption cannot be achieved without invoking ecological process. Leitner and Rosenzweig (1997) demonstrate that realistic species–area curves must include information about spatial heterogeneity. The curves obtained in this work did have finite asymptotes and variable curvatures. This work does

not, however, provide insights into the selection of log–log or log–linear models.

Birth Chains

Many different functions can exhibit similar asymptotic behavior and curvature. Suppose we select the candidate functions that fit the data best. Functions that give equally good fits to the data can make very different asymptotic predictions. One way to select among these candidate models would be to choose the model that best captures the mechanisms of species accumulation. Soberón and Llorente (1993) use the framework of birth chains for this purpose. Let $\{S(t): t \geq 0\}$ be the number of species observed by time t . Then $S(t)$ is a birth chain if

$$P\{S(t+dt) - S(t) = 1 | S(t)\} = \lambda(S(t), t)dt \quad (87)$$

$$P\{S(t+dt) - S(t) > 1\} = 0 \quad (88)$$

$$P\{S(0) = 0\} = 1 \quad (89)$$

This set of conditions means that the time between discoveries of new species is exponentially distributed. However, the rate at which new species occur depends on the time spent sampling and the number of species already found. The rate function, $\lambda(S, t)$, captures the details of the mechanism of species discovery. For example, suppose we assume that the rate of discovery declines linearly with species discovered. Then $\lambda(S, t) = a - bS(t)$. Soberón and Llorente (1993) show that

$$E[S(t)] = \frac{a}{b}(1 - e^{-bt}) \quad (90)$$

This method facilitates curve fitting because it allows us to derive expressions for the variance of $S(t)$. Existing methods that lack mechanistic foundations may be justified using this approach. For example, Soberón and Llorente (1993) provide insights into the popular Michaelis–Menten equation using this birth chain model.

Michaelis–Menten

The Michaelis–Menten equation has often been fitted to species accumulation data. It is a widely known function that has a finite asymptote, is nondecreasing, and accommodates a wide range of curvatures. The equation states that

$$S_{\text{obs}}(t) = \frac{at}{1 + bt} \quad (91)$$

Soberón and Llorente (1993) use a birth chain model to suggest a mechanistic basis for the Michaelis–Menten equation. The birth chain model assumes that the number of new species found is an inhomogeneous Poisson process with rate

$$\lambda(S, t) = a + \frac{b^2}{a} \frac{at}{1 + bt} - 2 \frac{b}{a} S \quad (92)$$

where j is the number of species found by time t and a and b are constants to be fit to the data. Soberón and Llorente

(1993) argue that if the chances of adding a new species improve with effort, to some upper limit, then a form such as Eq. (92) obtains. The key drawback with this and other curve-fitting models is that we do not have a distribution for the changes in S_{obs} . This means that we cannot rationally assign different weights to the data during fitting.

Which Estimation Method to Use?

Many estimators have been put forth, leaving the investigator with the practical question of which estimators are appropriate for use with a given new data set. Two facts may give us confidence a priori in an estimator's applicability to a new data set. As mentioned previously, each estimator makes assumptions about properties of the community being sampled (e.g., variation in capture probabilities across species or samples) and the sampling strategy used. If the community sampled and the sampling procedures used satisfy the assumptions of the estimator, then we can have some confidence in applying that estimator to a new data set.

However, meeting a method's explicit assumptions is not always sufficient. Another difficulty with relying solely on the theoretical basis of estimators is the fact that one or more assumptions are often violated in the sampling of real communities. Thus, theoretical support alone may not justify the use of a particular estimation method.

A second way to have confidence a priori in an estimator is to know its performance on similar communities sampled using similar methods over similar scales. Evaluating estimator performance on data allows testing implicit assumptions. Also, many estimation methods (e.g., extrapolation) have little biology built in: They exist because they seem to work in a few cases, and our confidence in them may come only from verification with relatively complete data sets. One should take care, however, not to conclude too much about an estimator based on its performance on single data sets. Rather, only through comprehensive testing on real data sets from a variety of taxa, locations, and spatial/temporal scales, as well as testing on simulated data, will we gain insight into estimator performance.

Estimator Evaluation

Evaluation on Real Data and Simulated Data

The testing of estimators has used data from real communities and from computer simulation. Each type of data has advantages and drawbacks. Real data take considerable effort to obtain. As a result, replication of real data sets is difficult. Simulated data sets, on the other hand, can be turned out in comparatively large numbers. This allows replication of data and testing of various sampling strategies on the same data.

To test estimators effectively with data, we must have some idea of the true parameters underlying our data (otherwise, how do we know what estimators should predict?). With simulated data, each parameter's true value is known because it is either specified by the investigator or is directly measurable from the simulated community. With real data, the truth may be approximated by testing estimators on smaller sets of

data from communities in which the parameters are reasonably well-known from separate, intensive sampling.

Finally, there are many properties of ecological communities which are likely to influence estimator performance. These include factors such as species richness s , various properties of the species abundance distribution, intraspecific clumping, and interspecific associations. Each of these can vary widely. Simulated data allow us to explore large parts of this parameter space. More important, with simulated data we can cover the range corresponding to anticipated field conditions. This allows us to test and select estimators before taking them into the field. Nevertheless, only real data can tell us which parts of the vast parameter space are relevant. Thus, we cannot ignore either approach: The biological reality of actual data is complemented by the versatility of simulated data.

Some progress has been made in the evaluation of estimation methods with data. Every such study cannot be detailed here, and not enough work has been done to allow generalizations to be made. Chazdon *et al.* (1998) provide one useful example of an approach combining both real and simulated data. They examined the performance of eight estimators using young woody regeneration in six tropical forest sites. Noticing that patchiness (intraspecific clumping) varied across sites, they then resampled the data sets to create simulated data sets with a range of patchiness levels. Testing estimators on these simulated data sets revealed the effect of patchiness on the performance of various estimators.

Estimator Evaluation Criteria

Clearly, one comprehensive study of the performance of all estimators over all possible data is impossible. Evaluation of estimators, then, will necessarily be done by many investigators with different communities and over different ranges of simulated data. To facilitate this cooperative approach, we must identify a common set of evaluation criteria that can be used to measure the performance of an estimator on a data set. These criteria are slightly different from theoretical properties of estimators. Numerous such criteria have been put forth; although they differ in calculation methods, they are often variants of a few common themes, which are listed as follows:

Bias: As defined previously, bias measures deviation from the true value. Common measures of bias include $E[S_{\text{est}}] - s$, or deviation from s , and $(E[S_{\text{est}}] - s)/s$, or relative deviation from s . In the evaluation of estimators with data, bias can be calculated as a mean across replicate data sets or can be assessed with increasing sample size within a data set.

Variance: As discussed previously, variance measures uncertainty in an estimate. If we have high variance, we can have little confidence that a single observation is a good indication of the mean. Variance may be calculated numerically over replicates, or an analytical estimator of variance may be used. These measures can also be expressed as confidence intervals and may be used in hypothesis testing when comparing estimated richnesses. Note that this measure does not depend on s , which is considered by other criteria.

Sample size independence: This measures the rate of convergence of an estimator's mean to its asymptotic value. An estimator that rapidly approaches its asymptotic value requires less sampling effort to obtain an equally good estimate. Such

an estimator is relatively sample size independent. This measure, too, does not depend on s .

Note that the previous three criteria may be calculated over multiple realizations of the same underlying parameters (e.g., the capture probabilities q_i). The following two may only be considered among multiple data sets in which these parameters vary.

Correlation with S : Since s is a fixed parameter, we introduce S as a random variable representing the true richness of any of a number of data sets, between which S and capture probabilities q_i may vary. If the correlation between an estimator S_{est} and true richness S across these data sets is high, S_{est} may be useful in comparing SR between sites or census occasions (Palmer, 1990). Note that correlation with S does not require that an estimator have low bias. Rather, correlation reflects a relative deviation of S_{est} from S that is somewhat constant across data sets.

Robustness: A robust estimator is one for which performance (as measured by any of the previous criteria) changes little across a range of data sets.

It is important to note that the relative importance of each of these criteria depends on the problem of interest. In measuring absolute species richness, minimizing bias may be a priority. In comparisons across time or space, variance and correlation with S become more important, whereas bias may become more tolerable. A final criterion represents a minimum requirement of sorts for estimator performance:

Beating S_{obs} : An estimator should perform better than S_{obs} , the number of species observed. Most estimators should have lower bias than S_{obs} most of the time. However, there are trade-offs. For example, the variance of some estimators may be higher than that of S_{obs} .

Selecting an Estimator

Although it is tempting to think that an estimator may exist which is robust to all census conditions, such an estimator is unlikely given the difficulty of the problem. Therefore, estimators should be chosen based on the context of the problem of interest. To select the estimators that are most likely to perform well on a new data set, one might use the following approach. First, consider the anticipated properties of a data set—based on knowledge of the system's biology—in relation to the modeling assumptions behind estimators. Select those estimators whose assumptions are best met by the expected data. If possible, select or modify the sampling strategy so that assumptions will be better met and/or more estimators may be used. Then, test estimators using data (simulated or previously existing) similar to that anticipated. The previous approach should indicate (i) which estimators might perform best on new data and (ii) whether these estimators perform well enough to meet the needs of the problem at hand. Although evaluating a number of estimators on multiple replicate data sets may seem a daunting task, computer programs (e.g., EstimateS, R. K. Colwell, <http://viceroj.eeb.uconn.edu/estimates>; WS2M, W. R. Turner *et al.*, unpublished) may be used to automate many of these calculations. However, use of such programs should complement, not replace, thoughtful

consideration of modeling assumptions, sampling design, and the biology of the community under study.

Glossary

Biotic similarity A measure of the degree to which two or more samples or assemblages are similar in species composition. Familiar biotic similarity indices include Sørensen's, Jaccard's, Horn's, and Morisita's indices.

Hill numbers A family of diversity measures developed by Mark Hill. Hill numbers quantify diversity in units of equivalent numbers of equally abundant species.

Individual-based (abundance) data A common form of data in biodiversity surveys. The data set consists of a vector of the abundances of different species. This data structure is used when an investigator randomly samples individual organisms in a biodiversity survey.

Nonparametric asymptotic estimators Estimators of total species richness (including Chao1, Chao2, abundance-based coverage estimator (ACE), incidence-based coverage estimator (ICE), and the jackknife) that do not assume a particular form of the species abundance distribution (such as a log-series or log-normal distribution). Instead, these methods use information on the frequency of rare species in a sample to estimate the number of undetected species in an assemblage.

Phylogenetic diversity Adjusted diversity measures that take into account the degree of relatedness among a set of species in an assemblage. Other things being equal, an assemblage of closely related species is less phylogenetically diverse than a set of distantly related species.

Rarefaction A statistical interpolation method of rarefying or thinning a reference sample by drawing random subsets of individuals (or samples) in order to standardize the comparison of biological diversity on the basis of a common number of individuals or samples.

Sample-based (incidence) data A common form of data in biodiversity surveys. The data set consists of a set of sampling units (such as plots, quadrats, traps, and transect lines). The incidence or presence of each species is recorded for each sampling unit.

Species accumulation curve A curve of rising biodiversity in which the *x*-axis is the number of sampling units (individuals or samples) from an assemblage and the *y*-axis is the observed species richness. The species accumulation curve rises monotonically to an asymptotic maximum number of species.

Species diversity A measure of diversity that incorporates both the number of species in an assemblage and some measure of their relative abundances. Many species diversity indices can be converted by an algebraic transformation to Hill numbers.

Species richness The total number of species in an assemblage or a sample. Species richness in an assemblage is difficult to estimate reliably from sample data because it is very sensitive to the number of individuals and the number of samples collected. Species richness is a diversity of order 0 (which means it is completely insensitive to species abundances).

Introduction

Measuring Biological Diversity

The notion of biological diversity is pervasive at levels of organization ranging from the expression of heat-shock proteins in a single fruit fly to the production of ecosystem services by a terrestrial ecosystem that is threatened by climate change. How can one quantify diversity in meaningful units across such different levels of organization? This article describes a basic statistical framework for quantifying diversity and making meaningful inferences from samples of diversity data.

In very general terms, a collection of "elements" are considered, each of which can be uniquely assigned to one of several distinct "types" or categories. In community ecology, the elements typically represent the individual organisms, and the types represent the distinct species. These definitions are generic, and typically are modified for different kinds of diversity studies. For example, paleontologists often cannot identify fossils to the species level, so they might study

diversity at higher taxonomic levels, such as genera or families. Population geneticists and molecular biologists might be interested in more fine-scale "omics" classifications of biological materials on the basis of unique DNA sequences (genomics), expressed mRNA molecules (transcriptomics), proteins (proteomics), or metabolic products (metabolomics). Ecosystem ecologists might be concerned not with individual molecules, genotypes, or species, but with broad functional groups (producers, predators, and decomposers) or specialized ecological or evolutionary life forms (understory forest herbs and filter-feeding molluscs). However, to keep things simple, this article will refer throughout to "species" as the distinct categories of biological classification.

Although the sampling unit is often thought of as the individual organism, many species, such as clonal plants or colonial invertebrates, do not occur as distinct individuals that can be counted. In other cases, the individual organisms, such as aquatic invertebrate larvae, marine phytoplankton, or soil microbes are so abundant that they cannot be practically counted. In these cases, the elements of biodiversity will

correspond not to individual organisms, but to the sampling units (traps, quadrats, and sighting records) that ecologists use to record the presence or absence of a species.

Species Richness and Traditional Species Diversity Metrics

The number of species in an assemblage is the most basic and natural measure of diversity. Many important theories in community ecology, including island biogeography, intermediate disturbance, keystone and foundational species effects, neutral theory, and metacommunity dynamics make quantitative predictions about species number that can be tested with field observations and experiments in community ecology. From the applied perspective, species richness is the ultimate “score card” in efforts to preserve biodiversity in the face of increasing environmental pressures and climate change resulting from human activity. Species losses can occur from extinction, and species increases can reflect deliberate and accidental introductions or range shifts driven by climate change.

Although species richness is a key metric, it is not the only component of species diversity. Consider two woodlands, each with 20 species of trees. In the first woodland, the 20 species are equally abundant, and each species comprises 5% of the total abundance. In the second woodland, one dominant species comprises 81% of the total abundance, and each of the remaining 19 species contributes only 1% to the total. Although both woodlands contain 20 species, a visitor to the first woodland would encounter most of the different tree species in a brief visit, whereas a visitor to the second woodland might encounter mostly the single dominant species (Figure 1).

Thus, a comprehensive measure of species diversity should include components of both species richness and the relative abundances of the species that are present. Such measures are

referred to in this article as “traditional” diversity measures. Ecologists have used dozens of different traditional diversity measures, all of which assume (1) individuals within a species are equivalent, (2) all species are “equally different” from one another and receive equal weighting, and (3) diversity is measured in appropriate units (individuals, biomass, and percentage cover are most commonly used).

Phylogenetic, Taxonomic, and Functional Diversity

As noted in the previous section the first assumption of traditional diversity metrics (individuals within a species are equivalent) can be relaxed by changing the operational definition of “species” to other categories of interest. The second assumption (all species are equally different from one another) ignores aspects of phylogenetic or functional diversity, but can also be incorporated through a generalization of traditional diversity metrics.

For example, consider two woodlands with identical tree species richness and evenness but with no shared species. The species in the first woodland are all closely related oaks in the same genus (*Quercus*). The species in the second woodland are a diverse mix of oaks (*Quercus*) and maples (*Acer*), as well as more distantly related pines (*Pinus*). Traditional species diversity metrics would be identical for both woodlands, but it is intuitive that the second woodland is more diverse (see Figure 2 for another example).

The concept of traditional diversity can therefore be extended to consider differences among species. All else being equal, an assemblage of phylogenetically or functionally divergent species is more diverse than an assemblage of closely related or functionally similar species. Differences among species can be based directly on their evolutionary histories, either in the form of taxonomic classification (referred to as taxonomic diversity) or phylogeny (referred to as phylogenetic

Community A: 20 species ($p_1 \dots p_{20} = 0.05$)

Sample #1: 20 individuals, 15 species observed, 5 species undetected

Sample #2: 20 individuals, 13 species observed, 7 species undetected

Community B: 20 species ($p_1 = 0.81, p_2 \dots p_{20} = 0.01$)

Sample #1: 20 individuals, 3 species observed, 17 species undetected

Sample #2: 20 individuals, 4 species observed, 16 species undetected

Figure 1 Species richness sampling in a hypothetical walk through the woods. Each different symbol represents one of 20 distinct species, and each row contains 20 characters, representing the first 20 individual trees that might be encountered in a random sample. Community A is maximally even, with each of the 20 species comprising 5% of the total abundance. In this assemblage, the two samples of 20 individual trees yielded 15 and 13 species, respectively. Community B is highly uneven, with one species (the open circle) representing 81% of the total abundance, and the remaining 19 species contributing only 1% each. In this assemblage, the two samples of 20 individual trees yielded only three and four species, respectively.

Figure 2 Phylogenetic diversity in species composition. The branching diagram is a hypothetical phylogenetic tree. The ancestor of the entire assemblage is the “root” at the top, with time progressing toward the branch tips at the bottom. Each node (branching point) represents a speciation or divergence event, and the 21 branch tips illustrate the 21 extant species. Extinct species or lineages are not illustrated. The five species in Assemblage I represent an assemblage of five closely related species (they all share a quite recent common ancestor). The five species in Assemblage II represent an assemblage of five distantly related species (they all share a much older common ancestor). All other things being equal, the community of distantly related species would be considered more phylogenetically diverse than the community of closely related species.

diversity (PD)) or indirectly, based on their function (referred to as functional diversity). These metrics relax the second assumption discussed in the section Species Richness and Traditional Species Diversity Metrics (all species are “equally different” from one another) by weighting each species by a measure of its taxonomic classification, phylogeny, or function.

Biotic Similarity

These concepts of species diversity apply to metrics that are used to quantify the diversity of single assemblages. However, the concept of diversity can also be applied to the comparison of multiple assemblages. Suppose again that a person visits two woodlands, both of which have 10 tree species, each species contributing 10% to the abundance of individual trees within the woodland. Thus, in terms of species richness and species diversity, the two woodlands are identical. However, the two woodlands may differ in their species composition. At one extreme, they may have no species in common, so they are biologically distinct, in spite of having equal species richness and species diversity. At the other extreme, if the list of tree species in the two woodlands is the same, they are identical in all aspects of diversity (including taxonomic, phylogenetic, and functional diversity). More typically, the two woodlands might have a certain number of species found in both woodlands and a certain number that are found in only one.

Biotic similarity quantifies the extent to which two or more sites are similar in their species composition and relative abundance distribution. The concept of biotic similarity is important at large spatial scales for the designation of biogeographic provinces that harbor distinctive species

assemblages with both endemic and shared elements. Biotic similarity is also a key concept underlying the measurement of beta diversity, the turnover in species composition among a set of sites. In an applied context, biotic similarity indices can quantify the extent to which distinct biotas in different regions have become homogenized through losses of endemic species and the introduction and spread of nonnative species. Differences among species in evolutionary histories and functional trait values can also be incorporated in similarity measures.

Bias in the Estimation of Diversity

The true species richness and relative abundances in an assemblage are unknown in most applications. Thus species richness, species diversity, and biotic similarity must be estimated from samples taken from the assemblage. If the sample relative abundances are used directly in the formulas for traditional diversity and similarity measures, the maximum likelihood estimator (MLE) of the true diversity or similarity measure is obtained. However, the MLEs of most species diversity measures are biased when sample sizes are small. When sample size is not sufficiently large to observe all species, the unobserved species are undersampled, and – as a consequence – the relative abundance of observed species, on average, is overestimated.

Because biotic diversity at all levels of organization is often high, and biodiversity sampling is usually labor intensive, these biases are usually substantial. Even the simplest comparison of species richness between two samples is complicated unless the number of individuals is identical in the two samples (which it never is) or the two samples represent the same degree of coverage (completeness) in sampling. Ignoring the sampling effects may obscure the influence of overall abundance or sampling intensity on species richness. Attempts to adjust for sampling differences by algebraic rescaling (such as dividing S by n or by sampling effort) lead to serious distortions and gross overestimates of species richness for small samples. Thus, an important general objective in diversity analysis is to reduce the undersampling bias and to adjust for the effect of undersampled species on the estimation of diversity and similarity measures. Because sampling variation is an inevitable component of biodiversity studies, it is equally important to assess the variance (or standard error) of an estimator and provide a confidence interval that will reflect sampling uncertainty.

The Organization of Biodiversity Sampling Data

This article introduces a common set of notation for describing biodiversity data (Colwell *et al.*, 2012). Consider an assemblage consisting of N^* total individuals, each belonging to one of S distinct species. Species i has N_i individuals, so that $\sum_{i=1}^S N_i = N^*$. The relative frequency p_i of species i is N_i/N^* , so that $\sum_{i=1}^S p_i = 1$. Note here that N^* , S , N_i , and p_i represent the “true” underlying abundance, species richness, and relative frequencies of species. These quantities are unknowns, but can be estimated, and one can make statistical inferences by taking

random samples of data from such an assemblage. This article distinguishes between two sampling structures.

Individual-Based (Abundance) Data

The *reference sample* is a collection of n individuals, drawn at random from the assemblage with N^* total individuals. In the reference sample, a total of S_{obs} species are observed, with X_i individuals observed for species i , so that $\sum_{i=1}^S X_i = n$ (only species with $X_i > 0$ contributes to the sum). Thus, the data consist of a single vector of length S , whose elements are the observed abundances of the individual species X_i . In this vector, there are S_{obs} nonzero elements.

The *abundance frequency count* f_k is defined as the number of species each represented by exactly k individuals in the reference sample. Thus, f_1 is the number of species represented by exactly one individual ("singletons") in the reference sample, and f_2 is the number of species represented by exactly two individuals ("doubletons"). In this terminology, f_0 is the number of *undetected species*: species that are present in the assemblage of N^* individuals and S species, but were not detected in the reference sample of n individuals and S_{obs} species. Therefore, $S_{\text{obs}} + f_0 = S$.

Sample-Based (Incidence) Data

The reference sample for incidence data consists of a set of R replicate *sampling units* (traps, plots, quadrats, search routes, etc.). In a typical study, these sampling units are deployed randomly in space within the area encompassing the assemblage. However, in a temporal study of diversity, the R sampling units would be deployed in one place at different independent points in time (such as an annual breeding bird census at a single site). Within each sampling unit, the presence or absence of each species is recorded, but abundances or counts of the species present are not needed. The data are organized as a species-by-sampling-unit *incidence matrix*, in which there are $i = 1$ to S rows (species), $j = 1$ to R columns (sampling units), and the matrix entry $W_{ij} = 1$ if species i is detected in sampling unit j , and $W_{ij} = 0$ otherwise. If sampling is replicated in both time and space, the data would be organized as a three-dimensional matrix (species $\times$ sites $\times$ times). However, most biodiversity data sets are two dimensional, with either spatial or temporal replication, but not both.

The row sum of the incidence matrix $Y_i = \sum_{j=1}^R W_{ij}$ denotes the incidence-based frequency of species i for $i = 1$ to S . Y_i is analogous to X_i in the individual-based abundance vector. Species present in the assemblage but not detected in any sampling unit have $Y_i = 0$. The total number of species observed in the reference sample is S_{obs} (only species with $Y_i > 0$ contribute to S_{obs}).

The *incidence frequency count* Q_k is the number of species each represented exactly $Y_i = k$ times in the incidence matrix sample, $0 \leq k \leq R$. For the incidence matrix, $\sum_{k=1}^R kQ_k = \sum_{i=1}^S Y_i$ and $S_{\text{obs}} = \sum_{k=1}^R Q_k$. Thus, Q_1 represents the number of "unique" species (those that are each detected in only one sample) and Q_2 represents the number of "duplicate" species (those that are each detected in exactly two samples). The zero frequency Q_0 denotes the number of species among

the S species in the assemblage that were not detected in any of the R sampling units.

Species Richness Estimation

A simple count of the number of species in a sample is usually a biased underestimate of the true number of species, simply because increasing the sampling effort (through counting more individuals, examining more sampling units, or sampling a larger area) inevitably will increase the number of species observed. The effect is best illustrated in a *species accumulation curve*, in which the x -axis is the number of individuals sampled or sampling units examined and the y -axis is the number of species observed (Figure 3). The first individual sampled always yields one species, so the origin of an abundance-based species accumulation curve is the point $[1,1]$. If the next individual sampled is the same species, the curve stays flat with a slope of zero. If the next individual sampled is a different species, the curve rises to two species, with an initial slope of 1.0. Samples from the real world fall between these two idealized extremes, and the slope of the curve measured at any abundance level is the probability that the next individual sampled represents a previously unsampled species. The curve is steepest in the early part of the collecting, as the common species in the assemblage are detected relatively quickly. The curve continues to rise as

Figure 3 Species accumulation curve. The curve was generated by assuming an assemblage of 20 species whose relative abundances were created from a broken stick distribution (Tokeshi, 1999). The x -axis is the number of individuals sampled and the y -axis is the number of species observed. The species accumulation curve is the smooth red line, which represents the average of 1000 random draws, sampling with replacement, at each level of abundance. The shaded envelope represents a symmetric 95% bootstrap confidence interval, calculated from the estimated variance of the random draws. The shape of this species accumulation curve is typical: it rises rapidly at first as the common species are initially encountered, and then continues to rise very slowly, as much more sampling is needed to encounter all of the rare species. For random samples of 500 or more individuals, it is almost always the case that all 20 species are encountered.

more individuals are sampled, but the slope becomes shallower because progressively more sampling is required to detect the rare species. As long as the sampling area is sufficiently homogeneous, all of the species will eventually be sampled and the curve will flatten out at an asymptote that represents the true species richness for the assemblage. For incidence data, a similar accumulation curve can be drawn in which the x-axis represents the number of sampling units and the y-axis is the number of species recorded.

Interpolating Species Richness with Rarefaction

A single empirical sample of individuals or a pooled set of sampling units represents one point on the species accumulation curve, but the investigator has no way of directly determining where on the curve this point lies. To compare the richness of two different samples, they must be standardized to a common number of individuals, for abundance samples (Sanders, 1968; Gotelli and Colwell, 2001, 2011). Rarefaction represents an interpolation of a biodiversity sample to a smaller number of individuals for purposes of comparison among samples. Typically, the abundance of the larger sample is rarefied to the total abundance of the smaller sample to determine if species richness (or any other biodiversity index) differs for a common number of individuals (Figure 4). For incidence data, rarefaction interpolates between the reference sample and a smaller number of sampling units.

Let $S_{\text{ind}}(m)$ represent the expected number of species in a random sample of m individuals from the reference sample of

Figure 4 Standardized comparison of species richness for two individual-based rarefaction curves. The data represent summary counts of carabid beetles that were pitfall-trapped from a set of young pine plantations (<20 years old; upper curve) and a set of old pine plantations (20–60 years old; lower curve). The solid lines are the rarefaction curves, calculated from eqn [2], and the shaded polygons are the 95% confidence intervals, calculated from the unconditional variance eqn [5]. The young plantation samples contained 243 individuals representing 31 species, and the old plantation samples contained 63 individuals representing nine species. The dashed and dotted vertical line illustrates a species richness comparison standardized to 63 individuals, which was the observed abundance in the smaller of the two data sets. Data from Niemelä J, Haila Y, Halme E, *et al.* (1988) The distribution of carabid beetles in fragments of old coniferous taiga and adjacent managed forest. *Annales Zoologici Fennici* 25: 107–199.

n individuals ($m < n$). If the true probabilities ($p_1, p_2, \dots, p_s$) of each of the S species in the assemblage were known, and species frequencies ($X_1, X_2, \dots, X_S$) follow a multinomial distribution for which the total of all frequencies is n , and cell probabilities ($p_1, p_2, \dots, p_S$), then

$$S_{\text{ind}}(m) = S - \sum_{i=1}^S (1 - p_i)^m \quad [1]$$

However, the true p_i values are unknown, and there is only the reference sample with observed species abundances X_i . An unbiased estimator for $S_{\text{ind}}(m)$ (Hurlbert, 1971) is

$$\tilde{S}_{\text{ind}}(m) = S_{\text{obs}} - \sum_{X_i > 0} \left[\binom{n - X_i}{m} / \binom{n}{m} \right] \quad [2]$$

For incidence-based data, the corresponding equation (Shinozaki, 1963) is

$$\tilde{S}_{\text{sample}}(r) = S_{\text{obs}} - \sum_{Y_i > 0} \left[\binom{R - Y_i}{r} / \binom{R}{r} \right] \quad [3]$$

where $r < R$ is the number of sampling units in the rarefied reference sample. The statistical model for rarefaction is sampling without replacement from the reference sample.

If the area of each of the sample plots has been measured, species richness can also be interpolated from a *Coleman curve*, in which the expected species richness on an island (or sample plot) of area a is based on a Poisson model and is a function of the total area A of the archipelago (or the summed areas of all the sample plots) (Coleman *et al.*, 1982):

$$\tilde{S}_{\text{area}}(a) = S_{\text{obs}} - \sum_{X_i > 0} \left(1 - \frac{a}{A} \right)^{X_i} \quad [4]$$

Although the variance from the hypergeometric distribution has traditionally been used to calculate a confidence interval for a rarefaction curve, this variance is conditional on the observed sample. It therefore has the undesirable property of converging to zero when the abundance level reaches the reference sample size. More realistically, the observed sample is itself drawn from a much larger assemblage, so the confidence intervals generally should widen as the reference sample size is reached. This unconditional variance for abundance data is calculated as follows (Colwell *et al.*, 2012):

$$\sigma_{\text{ind}}^2(m) = \sum_{k=1}^n (1 - \alpha_{km})^2 f_k - [\tilde{S}_{\text{ind}}(m)]^2 / S_{\text{est}} \quad [5]$$

where S_{est} denotes an estimated species richness (such as Chao1, described in the section Species Richness Estimation)

and $\alpha_{km} = \binom{n-k}{m} / \binom{n}{m}$ for $k \leq n - m$, $\alpha_{km} = 0$ otherwise.

The corresponding unconditional variance for incidence data is (Colwell *et al.*, 2004)

$$\sigma_{\text{sample}}^2(r) = \sum_{k=1}^R (1 - \beta_{kr})^2 Q_k - [\tilde{S}_{\text{sample}}(r)]^2 / S_{\text{est}} \quad [6]$$

where S_{est} denotes a sample-based estimated species richness (such as Chao2, described in the section Species Richness

Estimation) and $\beta_{kr} = \binom{R-k}{r} / \binom{R}{r}$ for $k \leq R-r$, $\beta_{kr}=0$

otherwise. These variances allow for the calculation of 95% confidence intervals on expected species richness for any abundance level smaller than the observed sample (Figure 4).

Because all rarefaction curves converge at small sample sizes toward the point [1,1] (for abundance data) or a small number of species (for incidence data), sufficient sampling is necessary for valid comparisons of curves. Although there are no theoretical guidelines, empirical examples suggest that samples of at least 20–50 individuals per sample (and preferably many more) are necessary for meaningful comparisons of abundance-based rarefaction curves.

Rarefaction curves also require comparable sampling methods (forest samples collected from pitfall traps cannot be validly compared to prairie samples collected from baits), well-defined assemblages of discrete countable individuals (for abundance-based methods), random spatial arrangement of individuals, and random, independent sampling of individuals (or larger sampling units for incidence-based methods). If the spatial distribution of individuals is intraspecifically clumped in space, abundance-based rarefaction will overestimate species richness, but this problem can be effectively countered by increasing the spatial grain of sampling or using incidence-based methods. Perhaps the chief disadvantage of rarefaction is that point comparisons force an investigator to rarefy all samples down to the smallest sample size in the data set, so sufficient sampling is important. However, calculation and comparison of complete rarefaction curves and their extrapolation, with unconditional variances, help to overcome this problem (Colwell *et al.*, 2012).

Nonparametric Asymptotic Species Richness Estimators

Whereas rarefaction is a method for interpolating species diversity data, asymptotic richness estimators are methods for extrapolating species diversity out to the (presumed) asymptote, beyond which additional sampling will not yield any new species. Three strategies have been used to try to estimate the asymptote of the species accumulation curve. *Parametric curve fitting* uses the shape of the species accumulation curve in its early phase to try and predict the asymptote. Asymptotic functions, such as the negative exponential distribution, the Weibull distribution, the logistic equation, and the Michaelis–Menten equation, are fit (usually with nonlinear regression methods) to the species accumulation data, and the asymptote can be estimated as one of the parameters of this kind of model. The chief problem is that this does not work well in comparisons with empirical or simulated data sets, mainly because it does not directly use information on the frequency of common and rare species, but simply tries to forecast the shape of the rising curve. Several different functional forms may fit the same data set equally well, but yield drastically different estimates of the asymptote. Because curve fitting is not based on a statistical sampling model, the variance of the resulting asymptote cannot be evaluated without further assumptions, and theoretical difficulties arise for model selection.

A second strategy is to use the abundance or incidence frequency counts (f_k or Q_k) and fit them to a *species abundance*

distribution, such as the log-series or the log-normal distribution. The area under such a fitted curve is an estimate of the total number of species present in the assemblage. The chief weakness of these methods is that simulations show that they work well only when the correct form of the species abundance distribution is already known, but this is never the case for empirical data. It is often not clear that existing statistical models fit empirical data sets very well, which often depart from expected values in the frequencies of the rare species. Moreover, there is no guarantee that two different assemblages follow the same kind of distribution, which complicates the comparison of curves.

The most successful methods so far have been *nonparametric estimators* (Colwell and Coddington, 1994), which use the rare frequency counts to estimate the frequency of the missing species (f_0 or Q_0). For incidence data, these estimators are similar to mark-recapture models that are used in demography to estimate the total population size and are based on statistical theorems developed by Alan Turing and I.J. Good from cryptographic analysis of Wehrmacht coding machines during World War II. The basic concept of their theorem is that abundant species – which are certain to be detected in samples – contain almost no information about the undetected species, whereas rare species – which are likely to be either undetected or infrequently detected – contain almost all the information about the undetected species.

If there are many undetectable or “invisible” species in a hyperdiverse assemblage, it will be impossible to obtain a good estimate of species richness. Therefore, an accurate lower bound for species richness is often of more practical use than an imprecise point estimate. Based on the concept that rare species carry the most information about the number of undetected species, the Chao1 estimator uses only the numbers of singletons and doubletons (and the observed richness) to obtain the following lower bound for the expected asymptotic species richness (Chao, 1984):

$$\hat{S}_{\text{Chao1}} = \begin{cases} S_{\text{obs}} + f_1^2/(2f_2) & \text{if } f_2 > 0 \\ S_{\text{obs}} + f_1(f_1 - 1)/2 & \text{if } f_2 = 0 \end{cases} \quad [7]$$

with an associated variance estimator of (if $f_2 > 0$)

$$\hat{v}ar(\hat{S}_{\text{Chao1}}) = f_2 \left[\frac{1}{2} \left(\frac{f_1}{f_2} \right)^2 + \left(\frac{f_1}{f_2} \right)^3 + \frac{1}{4} \left(\frac{f_1}{f_2} \right)^4 \right] \quad [8]$$

For incidence data, Chao2 is the corresponding estimator for species richness. It incorporates a sample-size correction factor $(R-1)/R$ (Chao, 1987):

$$\hat{S}_{\text{Chao2}} = \begin{cases} S_{\text{obs}} + [(R-1)/R]Q_1^2/(2Q_2) & \text{if } Q_2 > 0 \\ S_{\text{obs}} + [(R-1)/R]Q_1(Q_1 - 1)/2 & \text{if } Q_2 = 0 \end{cases} \quad [9]$$

with a variance estimator of (if $Q_2 > 0$)

$$\hat{v}ar(\hat{S}_{\text{Chao2}}) = Q_2 \left[\frac{A}{2} \left(\frac{Q_1}{Q_2} \right)^2 + A^2 \left(\frac{Q_1}{Q_2} \right)^3 + \frac{1}{4} A^2 \left(\frac{Q_1}{Q_2} \right)^4 \right] \quad [10]$$

where $A = (R-1)/R$. When $f_2=0$ in the Chao1 estimator or $Q_2=0$ in the Chao 2 estimator, the variance formulas in

eqns [9] and [10] need modification; the modified variances are available in Chao and Shen (2010).

The Chao1 estimator may be very useful for data sets in which it is too time consuming to count the frequencies of all abundance classes, but it is relatively easy to count just the number of singleton and doubleton species. Chao1 and Chao2 are intuitive and very easy to calculate, and often perform just as well as more complex asymptotic estimators.

A more general approach is to use information on the frequency of other rare species, not just singletons and doubletons. A cut-off value κ denotes frequencies of rare species (frequency $\leq \kappa$) and abundant species (frequency $> \kappa$). The cut-off $\kappa = 10$ works well with many empirical data sets.

Let the total number of observed species in the abundant species group be $S_{\text{abun}} = \sum_{i>\kappa} f_i$ and the number of observed species in the rare species group be $S_{\text{rare}} = \sum_{i=1}^{\kappa} f_i$. Define $n_{\text{rare}} = \sum_{i=1}^{\kappa} i f_i$ and the coverage estimate $\hat{C}_{\text{rare}} = 1 - f_1/n_{\text{rare}}$. Coverage is the estimated proportion of the total number of N^* individuals in the assemblage that is represented by the species recorded in the sample. It is a reliable measure of the degree of sample completeness. The *Abundance-based Coverage Estimator (ACE)* is (Chao, 2005)

$$\hat{S}_{\text{ACE}} = S_{\text{abun}} + \frac{S_{\text{rare}}}{\hat{C}_{\text{rare}}} + \frac{f_1}{\hat{C}_{\text{rare}}} \hat{\gamma}_{\text{rare}}^2 \quad [11]$$

where $\hat{\gamma}_{\text{rare}}^2$ is the square of the estimated coefficient of variation of the species relative abundances:

$$\hat{\gamma}_{\text{rare}}^2 = \max \left\{ \frac{S_{\text{rare}}}{\hat{C}_{\text{rare}}} \frac{\sum_{i=1}^{\kappa} i(i-1)f_i}{(\sum_{i=1}^{\kappa} i f_i)(\sum_{i=1}^{\kappa} i f_i - 1)} - 1, 0 \right\} \quad [12]$$

An approximate variance for the ACE can be obtained using a standard asymptotic approach.

For incidence data, there is a corresponding *Incidence-based Coverage Estimator (ICE)*. As with ACE, first a cut-off point κ is selected that partitions the data into an infrequent species group (incidence frequency not larger than κ) and a frequent species group (incidence frequency larger than κ). The cut-off $\kappa = 10$ is recommended. Denote the number of species in the frequent group by $S_{\text{freq}} = \sum_{i>\kappa} Q_i$ and the number of species in the infrequent group by $S_{\text{infreq}} = \sum_{i=1}^{\kappa} Q_i$. The estimated sample coverage for the infrequent group is $\hat{C}_{\text{infreq}} = 1 - Q_1/\sum_{i=1}^{\kappa} i Q_i$. Let the number of sampling units that include at least one infrequent species be R_{infreq} . Then ICE is expressed as

$$\hat{S}_{\text{ICE}} = S_{\text{freq}} + \frac{S_{\text{infreq}}}{\hat{C}_{\text{infreq}}} + \frac{Q_1}{\hat{C}_{\text{infreq}}} \hat{\gamma}_{\text{infreq}}^2 \quad [13]$$

where $\hat{\gamma}_{\text{infreq}}^2$ is the squared estimate of the coefficient of variation of the species relative incidences:

$$\hat{\gamma}_{\text{infreq}}^2 = \max \left\{ \frac{S_{\text{infreq}}}{\hat{C}_{\text{infreq}}} \frac{R_{\text{infreq}}}{(R_{\text{infreq}} - 1)} \times \frac{\sum_{i=1}^{\kappa} i(i-1)Q_i}{(\sum_{i=1}^{\kappa} i Q_i)(\sum_{i=1}^{\kappa} i Q_i - 1)} - 1, 0 \right\} \quad [14]$$

In addition to Chao1, Chao2, ACE, and ICE, the *jackknife* method provides another class of nonparametric estimators of asymptotic species richness. Jackknife techniques were

developed as a general method to reduce the bias of a biased estimator. Here the biased estimator is the number of species observed in the sample. The basic idea with the j th-order jackknife method is to consider subdata by successively deleting j individuals from the data. The first-order jackknife turns out to be

$$\hat{S}_{jk1} = S_{\text{obs}} + \frac{n-1}{n} f_1 \approx S_{\text{obs}} + f_1 \quad [15a]$$

That is, only the number of singletons is used to estimate the number of unseen species. The second-order jackknife estimator, which uses singletons and doubletons, has the following form:

$$\hat{S}_{jk2} = S_{\text{obs}} + \frac{2n-3}{n} f_1 - \frac{(n-2)^2}{n(n-1)} f_2 \approx S_{\text{obs}} + 2f_1 - f_2 \quad [15b]$$

Higher-order jackknife estimators are available, although they give increasingly less weight to the more common species frequencies.

For replicated incidence data, the first-order jackknife for R samples is

$$\hat{S}_{jk1} = S_{\text{obs}} + \frac{R-1}{R} Q_1 \quad [16a]$$

and the second-order jackknife is

$$\hat{S}_{jk2} = S_{\text{obs}} + \frac{2R-3}{R} Q_1 - \frac{(R-2)^2}{R(R-1)} Q_2 \quad [16b]$$

All jackknife estimators can be expressed as linear combinations of frequency counts, and thus approximate variances and confidence intervals can be directly obtained.

Extrapolating Species Richness

Based on a reference sample of n individuals, the extrapolation or prediction problem is to estimate the expected number of species $S_{\text{ind}}(n+m^*)$ in an augmented sample of $n+m^*$ individuals from the assemblage ($m^*>0$). Under a simple multinomial model, Shen et al. (2003) derived the following useful predictor with an asymptotic variance:

$$\begin{aligned} \tilde{S}_{\text{ind}}(n+m^*) &= S_{\text{obs}} + \hat{f}_0 \left[1 - \left(1 - \frac{f_1}{n\hat{f}_0} \right)^{m^*} \right] \\ &\approx S_{\text{obs}} + \hat{f}_0 \left[1 - \exp \left(-\frac{m^* f_1}{n\hat{f}_0} \right) \right] \end{aligned} \quad [17]$$

where $\hat{f}_0$ is an estimator for f_0 (the number of undetected species). It is suggested that $\hat{f}_0$ can be obtained by using either the Chao1 estimator ($\hat{f}_0 = \hat{S}_{\text{Chao1}} - S_{\text{obs}}$) or the ACE estimator ($\hat{f}_0 = \hat{S}_{\text{ACE}} - S_{\text{obs}}$).

The corresponding extrapolation formula and its asymptotic variance for the Coleman area-based Poisson sampling model were developed by Chao and Shen (2004). An estimator for the expected number of species $S_{\text{area}}(A+a^*)$ in an

augmented area $A + a^*$ ($a^* > 0$) based on a reference sample of area A is

$$\tilde{S}_{\text{area}}(A + a^*) = S_{\text{obs}} + \hat{f}_0 \left[1 - \exp \left(-\frac{a^*}{A} \frac{f_1}{\hat{f}_0} \right) \right] \quad [18]$$

where $\hat{f}_0$ is the same as in the individual-based model.

For sample-based data with R sampling units comprising the reference sample, Chao *et al.* (2009, Appendix A) developed a Bernoulli-product model and derived the following estimator for the expected number of species $S_{\text{sample}}(R + r^*)$ in an augmented set of $R + r^*$ sampling units ($r^* > 0$) from the assemblage:

$$\begin{aligned} \tilde{S}_{\text{sample}}(R + r^*) &= S_{\text{obs}} + \hat{Q}_0 \left[1 - \left(1 - \frac{Q_1}{Q_1 + R\hat{Q}_0} \right)^{r^*} \right] \\ &\approx S_{\text{obs}} + \hat{Q}_0 \left[1 - \exp \left(\frac{-r^* Q_1}{Q_1 + R\hat{Q}_0} \right) \right] \end{aligned} \quad [19]$$

Here $\hat{Q}_0$, which is an estimator for Q_0 , can be obtained from either the Chao2 estimator ($\hat{Q}_0 = \hat{S}_{\text{Chao2}} - S_{\text{obs}}$) or the ICE ($\hat{Q}_0 = \hat{S}_{\text{ICE}} - S_{\text{obs}}$).

For each of these models, Colwell *et al.* (2012) linked the interpolation (rarefaction) curve and the corresponding

extrapolation (prediction) curve to yield a single smooth curve meeting at the reference sample (Figure 5). They also derived 95% (unconditional) confidence intervals for the interpolated and extrapolated richness estimates. Thus, rigorous statistical comparison can be performed not only for rarefaction but also for extrapolated richness values. This link helps to avoid the problem of discarding data and information from larger samples that is necessary for comparisons using the traditional rarefaction method. However, the extrapolations become highly uncertain if they are extended beyond approximately double the reference sample size. For both individual- and sample-based data, the additional sample size needed, beyond the reference sample, to attain the estimated asymptotic species richness, or to detect a specified proportion of asymptotic richness, is provided in Chao *et al.* (2009) and Colwell *et al.* (2012).

Species Diversity

Species Diversity Metrics

Although species richness is the most popular and intuitive measure for characterizing diversity, the section Species Richness Estimation emphasizes that it is a very difficult parameter to estimate reliably from small samples, especially for hyper-diverse assemblages with many rare species. Species richness also does not measure the evenness of the species abundance distribution. Over the span of many decades, ecologists have proposed a plethora of diversity measures that incorporate both species richness and evenness, using both parametric and nonparametric approaches (Magurran, 2004).

For example, parametric approaches assume a particular species abundance distribution (such as the log-normal or gamma) or a species rank abundance distribution (such as the negative binomial or log series), and then estimate parameters from the distribution model that quantify the heterogeneity among species in their relative frequencies. However, as with the estimation of asymptotic richness, these methods often do not perform well unless the “true” species abundance distribution is known, which is never the case (Colwell and Codrington, 1994; Chao, 2005).

Nonparametric methods make no assumptions about the mathematical form of the underlying species abundance distribution, and they have been widely used not only in ecology but also in information science, economics, genetics, and linguistics (see Jost, 2007; Jost *et al.*, 2011; Chao and Jost, in press; Tuomisto, this volume for reviews). The most popular of these measures is the *Shannon entropy*,

$$H_{\text{Sh}} = - \sum_{i=1}^S p_i \log p_i \quad [20]$$

where S is the number of species in the assemblage and the i th species relative abundance is p_i . Shannon entropy quantifies the uncertainty in the species identity of a randomly chosen individual in the assemblage. Another measure that has been widely used in economics and genetics, as well as in ecology, is the Gini–Simpson index,

$$H_{\text{GS}} = 1 - \sum_{i=1}^S p_i^2 \quad [21]$$

Figure 5 A smoothed rarefaction and extrapolation curve. The x-axis is the number of individual, geo-referenced, dated ant specimens in New England, and the y-axis is the observed number of species. The total collection (the reference sample, filled circle) included 127 species and 20,225 individual records. The solid curve is the rarefaction curve interpolated from the reference sample. The dashed curve is the extrapolation, which extends to a minimum asymptotic estimator (Chao1) of ~135 species (open diamond). This number accords well with an independent estimate of an additional eight species that occur in suitable habitat in New York and Quebec. These eight species are likely to occur in New England, but so far they have not been collected. However, the extrapolation to reach the Chao1 estimator extends to over 70,000 museum records, and the confidence interval (shaded polygon) is therefore fairly broad. The data set was compiled from museum records and private collections of ants sampled throughout the New England states of the USA (RI, CT, MA, VT, NH, and ME) between 1900 and 2011. Data modified from Ellison AM, Gotelli NJ, Farnsworth EJ, and Alpert GD (2012) *A Field Guide to the Ants of New England*. New Haven, CT: Yale University Press.

which measures the probability that two randomly chosen individuals (selected with replacement) belong to two different species. The measure $1 - H_{GS} = \sum_{i=1}^S p_i^2$ is referred to as the Simpson index. With an adjustment for N^* , the total number of individuals in the assemblage, the Gini-Simpson index is closely related to the ecological index *PIE* (Hurlbert, 1971), the probability of an interspecific encounter:

$$PIE = [N^*/(N^* - 1)]H_{GS} \quad [22]$$

which measures the probability that two randomly chosen individuals (selected *without* replacement) belong to two different species. Both *PIE* and the Gini-Simpson index have a straightforward interpretation as a probability. When *PIE* is applied to species abundance data, it is equivalent to the slope of the individual-based rarefaction curve measured at its base.

However, the units of the Gini-Simpson index and *PIE* are probabilities that are bounded between 0 and 1, and the units of Shannon entropy are logarithmic units of information. These popular complexity measures do not behave in the same intuitive way as species richness (Jost, 2007).

The ecologist MacArthur (1965) was the first to show that Shannon entropy (when computed using natural logarithms) can be transformed to its exponential $\exp(H_{sh})$, and the Gini-Simpson index can be transformed to $1/(1 - H_{GS}) = 1/\sum_{i=1}^S p_i^2$, yielding two new indices that measure diversity in units of species richness. In particular, these transformed indices measure diversity in units of “effective number of species” – the equivalent number of equally abundant species that would be needed to give the same value of the diversity measure. When all species are equally abundant, the effective number of species is equal to the richness of the assemblage.

These converted measures, like species richness itself, satisfy an important and intuitive property called the “replication principle” or the “doubling property” (Hill, 1973): if N equally diverse assemblages with no shared species are pooled in equal proportions, then the diversity of the pooled assemblage should be N times the diversity of each single assemblage. Simple examples show that Shannon’s entropy and Gini-Simpson measures do not obey the “replication principle.” However the transformed values of these indices do obey the replication principle.

Hill Numbers

The ecologist Mark Hill incorporated the transformed Shannon and Gini-Simpson measures, along with species richness, into a family of diversity measures later called “Hill numbers,” all of which measure diversity as the effective number of species. Different Hill numbers qD are defined by their “order” q as (Hill, 1973)

$$^qD = \left(\sum_{i=1}^S p_i^q \right)^{1/(1-q)} \quad [23a]$$

This equation is undefined for $q=1$, but in the limit as q tends to 1:

$$^1D = \lim_{q \rightarrow 1} ^qD = \exp \left(- \sum_{i=1}^S p_i \log p_i \right) = \exp(H_{sh}) \quad [23b]$$

The parameter q controls the sensitivity of the measure to species relative abundance. When $q=0$, the species relative abundances do not count at all (no “discounting” for uneven abundances), and 0D equals species richness. When $q=1$, the Hill number 1D is the exponential form of Shannon entropy, which weighs species in proportion to their frequency and can be roughly interpreted as the number of “typical species” in the assemblage (Chao *et al.*, 2010; Chao and Jost, *in press*). When $q=2$, 2D equals $1/(1 - H_{GS})$, which heavily weights the most common species in the assemblage; the contribution from rare species is severely discounted. The measure 2D can be roughly interpreted as the number of “very abundant species” in the assemblage. Because all Hill numbers of higher order place increasingly greater weight on the most abundant species, they are much less sensitive to sample size (number of individuals or plots surveyed) than the most popular Hill numbers ($q=0, 1, 2$). Hill numbers with negative exponents can also be calculated, but they place so much weight on rare species they have poor sampling properties.

Thus, the measure of diversity using Hill numbers can potentially depend on the order q that is chosen. However, because all Hill numbers need not be integers, and all have common units of species richness, they can be portrayed on a single graph as a function of q . This “diversity profile” of effective species richness versus q portrays all of the information about species abundance distribution of an assemblage (Figure 6). The diversity profile curve is a decreasing function of q (Hill, 1973). The more uneven the distribution of relative abundances, the more steeply the curve declines. For a perfectly even assemblage, the profile curve is a constant at the level of species richness.

Estimation of Hill Numbers

All of the Hill numbers (including species richness) as well as the untransformed Gini-Simpson index and Shannon entropy are sensitive to the number of individuals and samples collected. The sample-size dependence diminishes as q increases because the higher-order Hill numbers are more heavily weighted by frequencies of common species, and the estimates of those frequencies are not very sensitive to sample size. In contrast, with increasing numbers of individuals or samples collected, rare species continue to be added to the sample, making richness and other low Hill numbers more sample size dependent.

The MLE for the Gini-Simpson index, $\hat{H}_{GS,MLE} = 1 - \sum_{i=1}^S (X_i/n)^2$, is biased downward, and the bias in some cases can be substantial. The minimum variance unbiased estimator (MVUE) of the Gini-Simpson index has the following relationship to its MLE:

$$\begin{aligned} \hat{H}_{GS,MVUE} &= 1 - \sum_{i=1}^S [X_i(X_i - 1)]/[n(n - 1)] \\ &= [n/(n - 1)]\hat{H}_{GS,MLE} \end{aligned} \quad [24a]$$

This MVUE is equivalent to the estimator of *PIE* and is relatively invariant to sample size. Thus, a nearly unbiased estimator for Hill number of order 2 is

$$^2\hat{D} = 1 / \sum_{i=1}^S [X_i(X_i - 1)]/[n(n - 1)] \quad [24b]$$

Figure 6 Diversity profile for assemblages of differing evenness. The x-axis is the order q in the Hill number (eqn [23a]), and is illustrated for values of q from 0 to 5. The y-axis is the calculated Hill number (the equivalent number of equally abundant species). Each of the four assemblages has exactly 100 species and 500 individuals, but they differ in their relative evenness: (1) completely even assemblage (black solid line): each species is represented by five individuals; (2) slightly uneven assemblage (red dashed line): 50 species each represented by seven individuals and 50 species each represented by three individuals (this structure is denoted as $\{50 \times 7, 50 \times 3\}$); (3) moderately uneven assemblage (green dotted line): $\{22 \times 10, 28 \times 5, 40 \times 3, 10 \times 2\}$; (4) highly uneven assemblage (blue dash-dot line): $\{1 \times 120, 1 \times 80, 1 \times 70, 1 \times 50, 3 \times 20, 3 \times 10, 90 \times 1\}$. For $q=0$, the Hill number is species richness, which is equal to 100 for all assemblages. Because Hill numbers represent the equivalent number of equally abundant species, the curve for the perfectly even assemblage (black solid line) does not change as q is increased. Larger values of q place progressively more weight on common species, so the equivalent number of equally abundant species is much lower for the more uneven assemblages than for more even assemblages.

For an integer $q \geq 2$, a similar derivation leads to a nearly unbiased estimator for qD .

$${}^q\hat{D} = \left\{ \sum_{i=1}^S [X_i(X_i - 1) \cdots (X_i - q + 1)] / [n(n-1) \cdots (n-q+1)] \right\}^{1/(1-q)} \quad [24c]$$

These estimators for $q \geq 2$ are almost independent of sample size, because all the higher-order Hill numbers are mainly dominated by the number of very abundant species. The estimated diversity profile curve is thus generally slowly varying for $q \geq 2$.

The estimation of entropy has been well studied in information science, physics, and statistics. Unfortunately, an unbiased estimator for Shannon entropy does not exist for any fixed sample size of n . As noted earlier, using X_i/n as a simple estimator of the true p_i value yields the MLE of entropy, which is negatively biased. An estimator of Shannon entropy with low bias is the following Horvitz–Thompson-type estimator

(Chao and Shen, 2003):

$$\hat{H}_{\text{Sh}} = - \sum_{i=1}^S \frac{\tilde{p}_i \log(\tilde{p}_i)}{1 - (1 - \tilde{p}_i)^n} \quad [25a]$$

where $\tilde{p}_i = (X_i/n)(1 - f_1/n)$ is an estimator of the true p_i . Only the detected species contribute to the summation because $\tilde{p}_i = 0$ for any undetected species. The denominator $1 - (1 - \tilde{p}_i)^n$ is the estimated probability that the i th species is detected in the sample, and the inverse of this probability is used as a weight for the i th species. Thus, the larger the probability of detection, the smaller the weight in the Horvitz–Thompson estimator. The weights adjust the estimator to compensate for missing species. For $q=1$, a low-bias estimator of the Hill number is

$${}^1\hat{D} = \exp \left(- \sum_{i=1}^S \frac{\tilde{p}_i \log(\tilde{p}_i)}{1 - (1 - \tilde{p}_i)^n} \right) \quad [25b]$$

In summary, the statistical properties of Hill numbers depend on the order q . Equation [24b] is a nearly unbiased estimator of diversity for $q=2$, and eqn [25b] is a low-bias estimator for $q=1$. As discussed in the section Species richness estimation, total species richness (${}^0D=S$) is much more difficult to estimate because it is very sensitive to rare species that are often undetected, even in relatively large samples. Several nonparametric species richness estimators that can be used for estimating 0D are provided in the section Nonparametric Asymptotic Species Richness Estimators. Then an estimated diversity profile can be constructed by plotting $\{{}^q\hat{D}; q=0, 1, 2, 3, \dots\}$ with respect to q , based on estimators given in eqns [24b], [24c], and [25b]. The variance of each estimator in the profile can be approximated by a standard asymptotic method, and a 95% confidence interval can thus be constructed as the estimator ± 1.96 s.e. for each value of q , if the sample size is sufficiently large.

Taxonomic and PD

To quantify taxonomic or PD, species are placed on a branching tree (a cladogram) that describes their evolutionary relationships (Figure 2). The base of the tree represents the ancestral taxon, the branching forks (nodes) represent speciation or divergence events, the branch tips represent the contemporary species (not all of which may be represented in any particular assemblage), and time is measured in the vertical axis, increasing from the base of the tree to the branch tips. (For paleontological applications, the tips may be extinct lineages.) All other things being equal, an assemblage in which all the species are closely related and concentrated in one region of the tree should be less diverse than an assemblage in which the same number of species is widely distributed among distant branch tips of the tree.

This article distinguishes two types of phylogenetic trees: ultrametric and nonultrametric trees. A tree is called ultrametric if all branch tips are the same distance from the basal node. For example, if the branch lengths are proportional to divergence time, the tree is ultrametric. A Linnean taxonomic tree, in which species are simply classified into a taxonomic hierarchy (Kingdom, Phylum, Class, Order, Family, Genus, and

Species), can be regarded as a special case of an ultrametric tree. In contrast, if the branch lengths are proportional to the number of base-pair changes in a given gene, or some other measure of genetic or morphological change, some branch tips may be farther in absolute time from the basal node than other branch tips, and such trees are nonultrametric.

Pielou (1975) was the first to notice that the concept of diversity could be broadened to consider differences among species. The earliest taxonomic diversity measure is the *cladistic diversity* (CD), which is defined as the total number of taxa or nodes in a taxonomic tree that encompasses all of the species in the assemblage (Vane-Wright *et al.*, 1991). Another pioneering work is Faith's (1992) PD, which is defined as the sum of the branch lengths of a phylogeny connecting all species in the target assemblage. In both CD and PD, species abundances are not considered.

C.R. Rao's *quadratic entropy* was the first diversity measure that accounted for both phylogeny and species abundances (Rao, 1982). It is a generalization of the Gini-Simpson index:

$$Q_{\text{Rao}} = \sum_{i,j} d_{ij} p_i p_j \quad [26a]$$

where d_{ij} denotes the phylogenetic distance between species i and j , and p_i and p_j denote the relative abundance of species i and j . This index measures the average phylogenetic distance between any two individuals randomly selected from the assemblage. For the special case of no phylogenetic structure (all species are equally related to one another), $d_{ii}=0$ and $d_{ij}=1$ ($i \neq j$), and Q_{Rao} reduces to the Gini-Simpson index.

The *phylogenetic entropy* H_p is defined as a generalization of Shannon's entropy to incorporate phylogenetic distances among species (Allen *et al.*, 2009):

$$H_p = - \sum_i L_i a_i \log a_i \quad [26b]$$

where the summation is over all branches, L_i is the length of branch i , and a_i denotes the summed abundance of all species descended from branch i . The notation a (abundance) here is not the same as that (for area) in eqn [4].

The replication principle can be generalized to phylogenetic or functional diversity: When N completely distinct trees (no shared nodes during the fixed time interval of interest) with equal diversities are combined, the diversity of the combined tree is N times the diversity of any individual tree. Simple examples can show that neither Q_{Rao} nor H_p satisfies this replication principle. As with traditional diversity measures, Q_{Rao} and H_p can be transformed into measures that do obey the replication principle. In an ultrametric tree with tree height T^* (the time interval between the tree base and tips), the transformed measures are, respectively, $\exp(H_p/T^*)$ and $1/[1 - (Q_{\text{Rao}}/T^*)]$.

For ultrametric trees, in addition to the order q , a time parameter T is required to generalize Hill numbers to measure PD in an interval from $-T$ time steps to the present time. The generalized phylogenetic metric is a time-averaged measure of lineage diversity (Hill numbers) at any moment t over the time interval $[-T, 0]$. The lineage diversity ${}^qD(t)$ at any moment t is measured by taking a "cross-section" and finding the lineages that are intersected (Figure 7). The relative abundance of each lineage is defined as the sum of the relative abundances of all

Figure 7 Calculation of mean phylogenetic diversity and branch diversity. In this hypothetical rooted phylogenetic tree, the ancestor to the assemblage is depicted at the top, and there are three extant species living at the present, depicted at the bottom, with relative abundances $(p_1, p_2, p_3) = (0.2, 0.3, 0.5)$. The tree is ultrametric, so the total branch length from the ancestor to any descendant species in the present is the same. To evaluate the phylogenetic diversity at the time $T = 5$ time steps in the past, we first create the set B_T which includes five branches with lengths $(L_1, L_2, L_3, L_4, L_5) = (4, 1, 1, 3, 1)$ and the corresponding abundances $(a_1, a_2, a_3, a_4, a_5) = (p_1, p_2, p_3, p_2 + p_3, p_1 + p_2 + p_3)$. We next measure the lineage diversity ${}^qD(t)$ at any time steps $0 < t < T$. We use three different "sampling times" as examples; these three sampling times correspond to the three distinct assemblages that would be represented by diversity sampling at three points in the past. For the first sampling time, $t=0.5$, lineage diversity ${}^qD(t)$ is measured as the Hill numbers for three lineages (species) with relative abundances (p_1, p_2, p_3) ; for the second sampling time $t=3$, lineage diversity ${}^qD(t)$ is measured as the Hill numbers for two lineages (species) with relative abundances $(p_1, p_2 + p_3)$; for the third sampling time $t=4.5$, lineage diversity ${}^qD(t)$ is measured as the Hill numbers for only one lineage (species) with relative abundance $p_1 + p_2 + p_3 = 1$. The average of these Hill numbers ${}^qD(t)$ over the interval $[-T, 0]$ gives the *mean phylogenetic diversity* ${}^q\bar{D}(T)$ of order q over T time steps. The branch diversity is ${}^qPD(T) = T \times {}^q\bar{D}(T)$. These two diversities can be calculated for any fixed $T \geq 0$; their pattern as a function of T is plotted in Figure 8. (For example, if T is changed to the tree height $T^*=4$ (distance between tree base and tips), then the branch set includes four branches $(L_1, L_2, L_3, L_4) = (4, 1, 1, 3)$ with the corresponding abundances $(a_1, a_2, a_3, a_4) = (p_1, p_2, p_3, p_2 + p_3)$, and the lineage diversity is averaged over $[-4, 0]$ to obtain ${}^q\bar{D}(T^*)$ and ${}^qPD(T^*) = T^* \times {}^q\bar{D}(T^*)$.)

of the descendants of that lineage in the present-day assemblage. Thus, ${}^qD(t)$ can be quantified by a Hill number. The average of these Hill numbers ${}^qD(t)$ over the interval $[-T, 0]$ gives the *mean PD* of order q over T time steps (Chao *et al.*, 2010):

$${}^q\bar{D}(T) = \left\{ \sum_{i \in B_T} \frac{L_i}{T} a_i^q \right\}^{1/(1-q)} \quad [27]$$

where B_T denotes the set of all branches in the time interval $[-T, 0]$, L_i is the length (duration) of branch i in the set B_T , and a_i is the total abundance of extant species descending from branch i ; see Figure 7 for a hypothetical ultrametric tree.

This measure ${}^q\overline{D}(T)$ gives the mean effective number of maximally distinct lineages (or species) T time steps in the past. The diversity of a tree with ${}^q\overline{D}(T)=z$ in the time period $[-T, 0]$ is the same as the diversity of an assemblage consisting of z equally abundant and maximally distinct species with all branch lengths T .

The branch diversity or phylogenetic diversity ${}^q\text{PD}(T)$ of order q through T time steps before present is defined as the product of ${}^q\overline{D}(T)$ and T . The measure ${}^q\text{PD}(T)$ given below quantifies “the total effective number of lineage-lengths or lineage-time steps” (Chao *et al.*, 2010)

$${}^q\text{PD}(T) = T \times {}^q\overline{D}(T) = \left\{ \sum_{i \in B_T} L_i \left(\frac{a_i}{T} \right)^q \right\}^{1/(1-q)} \quad [28]$$

If $q=0$ and $T=T^*$ (tree height), then ${}^0\text{PD}(T)$ reduces to Faith’s PD. It also reduces to CD in a taxonomic tree if the branching

of each Linnaean taxonomic category is assigned a time step of unit length. A PD profile can be constructed by plotting both ${}^q\text{PD}(T)$ and ${}^q\overline{D}(T)$ as a function of T for $q=0, 1$, and 2 . It is also informative to construct another diversity profile by plotting ${}^q\text{PD}(T)$ and ${}^q\overline{D}(T)$ as a function of order q for some selected values of temporal perspective T . See Figure 8 for a numerical example. In most applications, ecologists are interested in the case $T=T^*$ (tree height) or the divergence time between the species group of interest and its nearest outgroup. The divergence time of the most recent common ancestor of all extant taxa is another useful comparison.

For nonultrametric trees, the time parameter T is generalized to $\bar{T}$, where $\bar{T} = \sum_{i \in B_{\bar{T}}} L_i a_i$ represents the abundance-weighted mean base change per species and $B_{\bar{T}}$ denote the set of branches connecting all focal species. The diversity of a nonultrametric tree with mean evolutionary change $\bar{T}$ is the same as that of an ultrametric tree with a time step $\bar{T}$.

Figure 8 Branch diversity profile and mean phylogenetic diversity profile. (a) Branch diversity profile of ${}^q\text{PD}(T)$ (upper left panel) and mean phylogenetic diversity (upper right panel) as a function of the number of time steps (T) in the past ($0 < T < 5$) for $q=0, 1$, and 2 , based on the structure of the phylogenetic tree in Figure 7, assuming $(p_1, p_2, p_3) = (0.2, 0.3, 0.5)$ and $(L_1, L_2, L_3, L_4, L_5) = (4, 1, 1, 3, 1)$. (b) Branch diversity profile of ${}^q\text{PD}(T)$ (lower left panel) as a function of order q for $T=4$ (tree height) and $T=5$ time steps, and mean phylogenetic diversity profile of (lower right panel) as a function of order q for $T=0, 4$, and 5 , assuming $(p_1, p_2, p_3) = (0.2, 0.3, 0.5)$ and $(L_1, L_2, L_3, L_4, L_5) = (4, 1, 1, 3, 1)$. The branch diversity for $T=0$ is 0 as all branch lengths are 0. The mean phylogenetic diversity for $T=0$ are the traditional Hill numbers for $(p_1, p_2, p_3) = (0.2, 0.3, 0.5)$.

Therefore, the diversity formula for a nonultrametric tree is obtained by replacing T in the ${}^q\overline{D}(T)$ and ${}^q\text{PD}(T)$ with $\overline{T}$. Equation [27] can also describe taxonomic diversity, if the phylogenetic tree is a Linnaean tree with L levels (ranks), and each branch is assigned unit length. It also describes functional diversity, if a dendrogram can be constructed from a trait-based distance matrix using a clustering scheme (Petchey and Gaston, 2002). Thus, Hill numbers can be effectively generalized to incorporate taxonomy, phylogeny, and function and provide a unified framework for measuring biodiversity (Chao and Jost, in press).

Estimation of phylogenetic and functional diversity from small samples has not been well studied. As with the estimation of simple Hill numbers, phylogenetic diversity ${}^q\overline{D}(T)$ and ${}^q\text{PD}(T)$ can be accurately estimated only for $q=2$. Like the Gini-Simpson index, the MVUE of Rao's quadratic entropy exists under a multinomial model:

$$\hat{Q}_{\text{MVUE}} = \sum_{i,j} d_{ij} X_i X_j / [n(n-1)] \quad [29]$$

Thus, ${}^2\overline{D}(T)$ and ${}^2\text{PD}(T)$ can be estimated by a nearly unbiased measure using this estimator based on the transformation ${}^2\overline{D}(T) = 1/[1 - (Q_{\text{Rao}}/T)]$. With sufficient sampling, these estimators of PD of order $q=2$ are almost independent of sample size. Further research is needed for the development of accurate estimators of PD measures with $q=1$ and 0.

Biotic Similarity

Incidence-Based Similarity Indices

The earliest published incidence-based measure of relative compositional similarity is the classic Jaccard index from 1900. A number of incidence-based similarity measures have been proposed since then (see Jost *et al.*, 2011, for a review). The Jaccard index and the Sørensen index (proposed in 1948) are the most widely used ones, and both were originally developed to compare the similarity of two assemblages. Let S_1 be the number of species in Assemblage 1, S_2 be the number of species in Assemblage 2, and S_{12} be the number of shared species. The Jaccard similarity index $= S_{12}/(S_1 + S_2 - S_{12})$ and the Sørensen similarity index $= 2S_{12}/(S_1 + S_2)$. A rearrangement of the Sørensen index $= 1/[0.5(S_{12}/S_1)^{-1} + 0.5(S_{12}/S_2)^{-1}]$ reveals that it is the harmonic mean of two proportions: S_{12}/S_1 (the proportion of the species in the first assemblage that are shared with the second) and S_{12}/S_2 (the proportion of the species in the second assemblage that are shared with the first). The Jaccard index compares the number of shared species to the total number of species in the combined assemblages, whereas the Sørensen index compares the number of shared species to the mean number of species in a single assemblage. The Jaccard index is thus a comparison based on total diversity, whereas the Sørensen index is a comparison based on local diversity.

When one assemblage is much richer than the other, both Sørensen and Jaccard indices become very small. Although the low similarity value reflects the true difference between the two assemblages, in some applications it can be more informative to normalize a similarity measure so that maximum

overlap $= 1.0$. Lennon *et al.* (2001) proposed such a modification to the Sørensen index, and it takes the form $S_{12}/\min(S_1, S_2)$; see Jost *et al.* (2011) for details and comparisons.

When more than two assemblages are compared, a typical approach is to use the average of all pairwise similarities as a measure of global similarity. However, the pairwise similarities calculated from data tend to be correlated and are not independent. Most importantly, pairwise similarities cannot fully characterize multiple-assemblage similarity when some species are shared across two, three, or more assemblages (Chao *et al.*, 2008). It is easy to construct numerical examples in which all pairwise similarities are identical in two sets of assemblages, but the global similarities for the two sets are different.

The two-assemblage incidence-based Jaccard and Sørensen indices have been extended to multiple assemblages. Assume that there are N assemblages and there are S_j species in the j th assemblage and S species in the combined assemblage. Let $\bar{S}$ denote the average number of species per assemblage. The multiple-assemblage Jaccard similarity index $= (\bar{S}/S - 1/N)/(1 - 1/N)$. The multiple-assemblage Sørensen similarity index $= (N - S/\bar{S})/(N - 1)$. When $N=2$, these two measures reduce to their classical two-assemblage measures. These two measures are decreasing functions of Whittaker's beta diversity for species richness, which is $S/\bar{S}$. When N assemblages are identical, beta diversity ($q=0$) is $S/\bar{S}=1$, and thus both Jaccard and Sørensen similarity indices $= 1$. When N assemblages are completely distinct (no shared species), beta diversity ($q=0$) is $S/\bar{S}=N$, and thus both Jaccard and Sørensen similarity indices $= 0$.

These incidence-based similarity indices are widely used in ecology and biogeography because of their simplicity and easy interpretation. In most ecological studies, these indices are estimated from observed richness in sample data. The resulting estimates are generally biased downward, and the bias increases when sample sizes are small or species richness is large. They could become biased upward when shared species are common and endemic species are very rare (Chao *et al.*, 2005, p. 149). The classic pairwise Jaccard and Sørensen similarity indices calculated from sample data generally underestimate the true similarity mainly because they do not account for shared species at both sites that were not detected. One strategy could be to use asymptotic species richness estimators (see Species Richness Estimation) to estimate species richness in each assemblage and also to estimate species richness in the combined assemblage, and then substitute the estimated values into the similarity formulas. However, this strategy inevitably inflates the variance and often renders the resulting estimate useless. A major statistical concern is that, based on incidence data alone, bias correction and measurements of variances are impossible. Consequently, the interpretation of any incidence-based index based on sample values or estimated values becomes difficult or misleading for comparing two (or more) highly diverse assemblages based on limited data. Only with abundance data can one correct for undersampling bias, as explained in the next section.

Classical incidence-based similarity indices treat abundant and rare species equally, which oversimplifies the relationships between assemblages. If species abundances can be measured, they should be used for a more accurate

representation (and better statistical estimation) of the similarity of assemblages.

Abundance-Based Similarity Indices

Assume that in the combined assemblages, there are S species. Denote the relative abundance vector for the S species in the j th assemblage by $(p_{1j}, p_{2j}, \dots, p_{Sj})$, some of them may be 0. Thus, for N assemblages, there are N sets of abundances $\{(p_{1j}, p_{2j}, \dots, p_{Sj}); j = 1, 2, \dots, N\}$. A sample of n_j individuals is taken from the j th assemblage and there are N sets of sample frequencies $\{(X_{1j}, X_{2j}, \dots, X_{Sj}); j = 1, 2, \dots, N\}$.

For two-assemblage cases, one of the most popular abundance-based similarity metric is the Horn overlap measure (Horn, 1966), which is based on Shannon's entropy:

$$S_H = \frac{1}{\log 2} \sum_{i=1}^S \left[\frac{p_{i1}}{2} \log \left(1 + \frac{p_{i2}}{p_{i1}} \right) + \frac{p_{i2}}{2} \log \left(1 + \frac{p_{i1}}{p_{i2}} \right) \right] \quad [30]$$

Another popular overlap measure is the Morisita–Horn similarity measure (Morisita, 1959), based on the Simpson index:

$$\begin{aligned} S_{MH} &= \frac{\sum_{i=1}^S p_{i1} p_{i2}}{\left[\sum_{i=1}^S p_{i1}^2 + \sum_{i=1}^S p_{i2}^2 \right] / 2} \\ &= 1 - \frac{\sum_{i=1}^S (p_{i1} - p_{i2})^2}{\sum_{i=1}^S p_{i1}^2 + \sum_{i=1}^S p_{i2}^2} \end{aligned} \quad [31]$$

Since each of the indices [30] and [31] equals unity if and only if $p_{i1} = p_{i2}$ for all i , these two indices match relative abundances on a species-by-species basis. When the two assemblages are equally diverse and consist entirely of equally common species, the Morisita–Horn index, the Horn index, and the Sørensen index are all equal, and all of these indices give the proportion of shared species in an assemblage.

The first expression in eqn [31] for the Morisita–Horn index has an important probabilistic interpretation. If one individual is selected randomly from each assemblage, then the probability that the two selected individuals belong to the same shared species is $\sum p_{i1} p_{i2}$, the numerator in eqn [31]. The denominator in eqn [31] represents a normalizing constant, which is the average of two such probabilities for two individuals drawn from the same assemblages. In this probabilistic interpretation, the abundant species will contribute the most to the probability that two randomly selected individuals belong to the same species. As a result, in a hyperdiverse assemblage, the index is dominated by a few abundant species and the relatively rare species (even if there are many of them) have little effect. The index is therefore likely to be resistant to undersampling, because the influential abundant species are always present in samples.

The following MLE of the Morisita–Horn index is always in the range $[0, 1]$, but it has been shown that this MLE systematically underestimates the true similarity.

$$\tilde{S}_{MH, MLE} = \frac{2 \sum_{i=1}^S (X_{i1}/n_1)(X_{i2}/n_2)}{\sum_{i=1}^S (X_{i1}/n_1)^2 + \sum_{i=1}^S (X_{i2}/n_2)^2} \quad [32]$$

A better estimator that is nearly unbiased has the following form, although it may exceed the theoretical maximum value of 1:

$$\tilde{S}_{MH} = \frac{2 \sum_{i=1}^S (X_{i1}/n_1)(X_{i2}/n_2)}{\sum_{i=1}^S (X_{i1}(X_{i1}-1)/(n_1(n_1-1))) + \sum_{i=1}^S (X_{i2}(X_{i2}-1)/(n_2(n_2-1)))} \quad [33]$$

It is statistically infeasible to derive analytic or asymptotic variance formulas for these two estimators and the other similarity estimators in this section. A bootstrap method, suggested in Chao *et al.* (2008), is a simple and direct data-resampling method to obtain approximate estimates of variances and confidence intervals especially for complex estimators (Efron and Tibshirani, 1993). This method has found wide applications in various disciplines.

To the extent that ecological processes are often most strongly influenced by abundant species, the Morisita–Horn measure is useful when looking for functional differences between ecosystems. However, when rare species are important, as in many conservation applications, the Horn overlap measure would be more useful. But the MLE of the Horn overlap measure exhibits moderate bias due to under-sampling. Until now, only the two-sample jackknife technique has been used to remove part of bias (Jost *et al.*, 2011). More research is required to find a reliable bias-reduced estimator.

For assessing similarity among more than two assemblages, a general multiple-assemblage, abundance-based overlap measure C_{qN} (Chao *et al.*, 2008) is

$$C_{qN} = \frac{[1/(N^q - N)] \sum_{i=1}^S [(p_{i1} + p_{i2} + \dots + p_{iN})^q - (p_{i1}^q + p_{i2}^q + \dots + p_{iN}^q)]}{(1/N) \sum_{i=1}^S (p_{i1}^q + p_{i2}^q + \dots + p_{iN}^q)} \quad [34]$$

As with the Hill numbers, here q is a parameter that determines the measure's sensitivity to species' relative abundances, and N is the number of assemblages. The C_{qN} measure includes, as special cases, the classic two-assemblage Sørensen index ($q=0, N=2$), the Horn overlap index ($q=1, N=2$), the Morisita–Horn similarity index ($q=2, N=2$), and their multiple-assemblage generalizations ($N > 2$) as follows:

For $q=0$, C_{0N} is the multiple-assemblage Sørensen similarity index:

$$C_{0N} = (N - S/\bar{S}) / (N - 1) \quad [35a]$$

For $q=1$, C_{1N} is the multiple-assemblage Horn overlap index:

$$C_{1N} = \frac{1}{\log N} \sum_{i=1}^S \sum_{j=1}^N \left[\frac{p_{ij}}{N} \log \left(1 + \frac{\sum_{k \neq j} p_{ik}}{p_{ij}} \right) \right] \quad [35b]$$

For $q=2$, C_{2N} is the multiple-assemblage Morisita–Horn similarity index:

$$C_{2N} = \frac{2 \sum_{i=1}^S \sum_{j < k} p_{ij} p_{ik}}{(N-1) \sum_{i=1}^S \sum_{j=1}^N p_{ij}^2} \quad [35c]$$

Jost (2007) was the first to develop a rigorous mathematical formulation of alpha and beta diversities based on Hill numbers of order q . He derived the multiplicative beta diversity ${}^qD_\beta$, which quantifies the effective number of completely distinct assemblages; see also Jost *et al.* (2011), Chao and Jost (in press), and Tuomisto (this volume) for reviews. For

equally weighted assemblages, beta diversity ${}^qD_\beta$ ranges between a minimum of 1 (when all assemblages are identical) and a maximum of N , the number of assemblages in each region (when all assemblages are completely distinct; i.e., there are no shared species). For example, a set of completely distinct sites in a region of three sites attains the maximum value of 3, whereas another set of completely distinct sites in a region of 10 sites attains the maximum value of 10. Because the maximum depends on the number of assemblages in the region, beta diversities usually cannot be compared directly among multiple regions. Instead, beta diversity should be compared with sample-based rarefaction to a common number of samples or to a common degree of completeness of samples in each region. However, beta diversity can be transformed to the C_{qN} measure in the range $[0, 1]$ by the following nonlinear transform for N equally weighted assemblages:

$$C_{qN} = [(1/q D_\beta)^{q-1} - (1/N)^{q-1}] / [1 - (1/N)^{q-1}] \quad [36]$$

The transformed measure C_{qN} is unity (when all assemblages are identical) and 0 (when all assemblages are completely distinct).

This nonlinear transformation ensures that C_{qN} preserves an essential property of an overlap index: The transformed index C_{qN} gives the true overlap A/S for all orders of q if N assemblages each have S equally common species, exactly A species are shared by all of them, and the remaining species

are not shared by any assemblages. No linear transformation of beta diversity can achieve this property. See Figure 9, Case I, for an example. The measure C_{qN} thus quantifies the *effective average overlap per assemblage*, i.e., average percentage of *overlapped species* (species that are shared by all assemblages, as defined in the above sense) in an assemblage. Because this measure is in a sense of “average” overlap, it can be compared across regions with different number of assemblages. See Chao *et al.* (2008) for more details on the interpretation of C_{qN} based on a simple reference set of assemblages.

Just as diversity profiles are used to characterize traditional diversity (Figure 6) and PD (Figure 8), Chao *et al.* (2008) suggest the use of a similarity profile $\{C_{qN}; q=0, 1, 2, \dots, N\}$ to describe similarity across N assemblages. It is recommended that investigators calculate at least C_{0N} , C_{1N} , and C_{2N} ; see Jost *et al.* (2011, p. 81) and Figure 9 for examples.

Because the overlap measure C_{qN} is constructed from Hill numbers of order q , the magnitude of the undersampling bias depends on the order q . As with Hill numbers, there exists a nearly unbiased estimator only for $q=2$:

$$\hat{C}_{2N} = \frac{2 \sum_{i=1}^S \sum_{j < k} (X_{ij}/n_j)(X_{ik}/n_k)}{(N-1) \sum_{i=1}^S \sum_{j=1}^N [X_{ij}(X_{ij}-1)/n_j(n_j-1)]} \quad [37]$$

This measure quantifies the similarity of relative frequencies for abundant species. A bootstrap variance estimator and the associated confidence interval are provided in Chao *et al.* (2008). Satisfactory estimators for C_{0N} and C_{1N} that characterize the similarity of relative frequencies for rare species are still lacking.

Figure 9 The two-assemblage similarity profile C_{qN} for $q=0, 1, 2$. **Case I:** In each of Assemblages 1 and 2, there are 20 equally abundant species, and eight species are shared. Thus, for all orders of q , the similarity measure C_{qN} equals the percentage of overlap in each assemblage. That is, $C_{qN}=8/20=40\%$ for all q (black solid line). **Case II:** In each of Assemblages 1 and 2, there are 20 species, and the relative abundances in each assemblage are $p_i \propto K/i$ for $i=1, 2, \dots, 20$, where K is a normalizing constant such that the total relative abundances is 1. Assume that the shared species are the most abundant eight species. The similarity measure C_{qN} increases as order q is increased (red dashed line). **Case III:** Same as in Case II, but the shared species are the rarest eight species. The similarity measure C_{qN} decreases as order q is increased (blue dotted line).

Similarity Indices Based on Total Abundance of Shared Species

As explained earlier, the Horn overlap measure (eqn [30]) and the Morisita–Horn similarity measure (eqn [31]) match species relative abundances, *species-by-species*. Hence, the typical similarity indices assess a normalized probability that two randomly chosen individuals, one from each assemblage, belong to the same species. Another approach by Chao *et al.* (2005) is to consider a (normalized) probability that both individuals, one from each of the two assemblages, both belong to *any* shared species (and not necessarily to the same shared species).

Let U denote the total relative abundances associated with the shared species in Assemblage 1 and let V denote the total relative abundances of the shared species in Assemblage 2. The Jaccard abundance-based similarity index is $UV/(U+V-UV)$ and the Sørensen abundance-based similarity index is $2UV/(U+V)$. These two shared-abundance indices are called the Chao–Jaccard abundance and Chao–Sørensen abundance indices in the literature and in the software package *EstimateS* (Colwell, 2011) and *SPADE* (Chao and Shen, 2010). This is because, when all species are equally common, $U=S_{12}/S_1$ and $V=S_{12}/S_2$ and the Chao–Jaccard abundance and Chao–Sørensen abundance indices reduce, respectively, to the classic incidence-based Jaccard and Sørensen indices. These two measures yield a maximum value of 1 when all species are shared (i.e., no unique species in both assemblages; $U=V=1$). Also, all indices tend to a minimum value of 0 for completely distinct assemblages (i.e., no shared species in both assemblages).

One advantage of these measures is that the undersampling bias due to unseen, shared species can be evaluated and corrected. Chao *et al.* (2005) used the frequencies of observed rare, shared species to obtain an appropriate adjustment term for U and V to account for the effect of *unseen* shared species and thus remove most undersampling bias. Then the bias-corrected U and V estimators are substituted into the formulas to obtain Chao–Jaccard and Chao–Sørensen estimators. These measures are designed to be sensitive to rare shared species while still taking abundance into account, so they may increase sharply as more shared species are discovered. Because these measures match the total relative abundances of species shared between two assemblages, they are useful if the focus is to construct abundance-based *complementarity* (dissimilarity or distance) measures by subtracting each measure from one. This class of measures can also be extended to replicated incidence data; see Chao *et al.* (2005) for details.

Phylogenetic Similarity Indices

The classic Jaccard, Sørensen, and Morisita–Horn similarity measures all have their own phylogenetic generalizations. Most of the pioneering work was developed by microbial ecologists (Lozupone and Knight, 2005; Faith *et al.*, 2009). The phylogenetic Jaccard and Sørensen measures are based on Faith’s total branch lengths and have formulas similar to their classic versions. The phylogenetic Sørensen index can be expressed as $2L_{12}/(L_1 + L_2)$, where L_1 and L_2 denote the total branch lengths in Assemblages 1 and 2, respectively, and L_{12} denotes the total length of the shared branches in the same time interval of interest (Lozupone and Knight, 2005). The phylogenetic Jaccard index takes the form of $L_{12}/(L_1 + L_2 - L_{12})$. When species relatedness is based on a simple Linnean taxonomic classification tree, L_1 and L_2 become the number of taxa in Trees 1 and 2, respectively, and L_{12} becomes the number of shared taxa in the pooled classification tree (Bacaro *et al.*, 2007). In these generalizations, “species” in the traditional indices are replaced by the total branch lengths (or the total number of nodes) in each assemblage. Also, “shared species” in the traditional indices are replaced by the total shared branch length (or the total number of shared nodes). In nearly all applications of these phylogenetic similarity indices, it is assumed that all species are observed; undersampling bias due to undetected species for these measures has not been discussed in this literature.

The classic Morisita–Horn measure has recently been generalized to its phylogenetic version (de Bello *et al.*, 2010). Let B denote the set consisting of all branches in the pooled assemblages in a specific time period of interest, and let the corresponding branch lengths in this set be $\{L_i; i \in B\}$. Assume that, in the j th assemblage, a_{ij} denotes the total relative abundance descended from Branch i , $i \in B$, $j = 1, 2, \dots, N$. The phylogenetic Morisita–Horn similarity for N assemblages is a generalization of eqn [35c] based on a normalized Rao’s quadratic entropy:

$$S_{MH}^* = \frac{2 \sum_{i \in B} \sum_{j < k} L_i a_{ij} a_{ik}}{(N-1) [\sum_{i \in B} \sum_{j=1}^N L_i a_{ij}^2]} \quad [38]$$

A nearly unbiased estimator for this measure is similar to that in eqn [37]. However, the measure in eqn [38] is valid only for

ultrametric trees. Extension to nonultrametric trees requires further research.

Modeling Biodiversity Dynamics in Countryside and Native Habitats

Henrique M Pereira and Luís Borda-de-Água, Faculdade de Ciências da Universidade de Lisboa, Lisboa, Portugal

© 2013 Elsevier Inc. All rights reserved.

Glossary

Biodiversity dynamics models Models describing the dynamics of one or more measures or dimensions of biodiversity (e.g., species diversity or population abundances).

Countryside habitats A landscape made of native and human-dominated habitats.

Human-dominated habitat A habitat that has been significantly altered by humans. Significant habitat alterations include the conversion of natural forest into a pasture or the reclamation of a wetland for agriculture.

Land use The set of human activities within a landscape and their impacts on natural processes, such as physical, chemical, and biological cycles. In practice, land use is often classified in major categories such as cropland, pasture, plantation forest, and natural forest.

Metapopulation model A model of a population restricted to habitat patches immersed in a matrix used only for dispersal. The population in each habitat patch may go extinct through stochastic processes and recolonized by individuals dispersing from other patches.

Native habitat Native habitat is the community of species and the physical environment that occurred in a region before human intervention. In this article, it is equated to

the naturally occurring vegetation in a region. In other contexts, it refers to the particular natural habitat of a given species.

Phenomenological models Models that relate observable variables without postulating the underlying (physical, biological, etc.) mechanisms. For example, the species–area relationship is a phenomenological model because it does not explicitly state the mechanisms leading to the relationship between the number of species and area.

Process-based models Models explicitly based on mathematical representations of processes or mechanisms, such as animal or seed dispersal. For example, population dynamics models describe the evolution over time of the population abundance by accounting for processes such as birth, death, and dispersal.

Species–area relationships The relationship between the size of a given habitat or area sampled across habitats, and the number of species (typically of a specific taxonomic group) found in that area.

Source-sink population model A model of a population that occupies multiple habitats in the landscape connected through dispersal. The habitats where population growth is positive are sources and the habitats where growth is negative are sinks.

Introduction

Despite international efforts and commitments to reduce biodiversity loss, biodiversity continues to decline at high rates compared to those in the background fossil record (Butchart *et al.*, 2010; Barnosky *et al.*, 2011). Land-use change is currently the main driver of biodiversity loss in terrestrial ecosystems and is likely to remain so over the next few decades (Duraiappah *et al.*, 2005; Pereira *et al.*, 2010). It is therefore essential to assess how different patterns of land-use affect biodiversity, in order to compare the biodiversity costs and benefits of different policy and management options.

Much of the recent modeling efforts on biodiversity dynamics of global change have looked at the impacts of climate change (Thuiller *et al.*, 2008; Pereira *et al.*, 2010). However, many of the original projections of global extinction rates were developed from forest loss estimates (Pimm *et al.*, 1995), and there is a renewed interest in models linking biodiversity response to land-use change at different scales (Pereira and Daily, 2006; Wright, 2010; He and Hubbell, 2011). Some of this renewed interest comes from the realization that although the conversion of native habitats to agriculture and other human-dominated habitats is followed by biodiversity loss (Brooks *et al.*, 1999, 2003), countryside habitats can also support important levels of biodiversity, particularly when forest patches or other complex vegetation features remain (Daily *et al.*, 2003;

Ranganathan *et al.*, 2008). Another important issue is that global land-use change dynamics are increasingly complex. While forest loss continues to occur in tropical forests and subtropical woodlands, some regions of the world are seeing an expansion of forest through natural vegetation regeneration or plantations (van Vuuren *et al.*, 2006; UNEP, 2007; FAO, 2010). Therefore, there is a need for models that can capture not only the biodiversity consequences of native forest loss, but also the potential benefits of natural forest expansion or the implications of forest plantations for biodiversity.

Here we review existing models to study the response of biodiversity to land-use change. These models can be grouped in two major categories: phenomenological and process-based (Pereira *et al.*, 2010). Phenomenological models use empirical relationships between habitat characteristics such as area and land-use intensity and species diversity or other biodiversity metrics. The most widely used phenomenological model is the species–area relationship (SAR), and it illustrates the approach of this type of model. There is a well-known relationship between the size of an area and the number of species in that area (Rosenzweig, 1995). The assumption is that the SAR can be applied to project the number of extinctions as a consequence of loss of area of native habitat, even if we do not explicitly model the processes that cause the relationship between the size of an area and its number of species. In contrast, process-based models try to capture the processes that

underlie the relationship between land use and biodiversity. For example source-sink models (Doak, 1995; Pereira *et al.*, 2004) describe the population dynamics of species in habitats of good quality and habitats of poor quality and the movement of individuals between those habitats. Land-use change modifies the proportion and the spatial configuration of the habitats in the landscape. Therefore, in source-sink models there is an explicit link between the land-use change processes and species population dynamics.

Phenomenological Models

Native Habitats: Species–Area Relationship

It has been long known by ecologists that the number of species in a given area increases with the size of the area (Arrhenius, 1921). Several expressions have been proposed to describe the relationship between number of species, S , and the size of an area, A , with the most common one being the power law (Dengler, 2009):

$$S(A) = cA^z \quad [1]$$

where z depends on the sampling regime and scale and c depends on the taxonomic group and region (Rosenzweig, 1995). Therefore, if there is a habitat loss of area a from a total area A , the proportion of species going extinct can be estimated as

$$\frac{S(A) - S(A - a)}{S(A)} = 1 - \left(1 - \frac{a}{A}\right)^z \quad [2]$$

The problem is that, in general, (1) is estimated from patterns that were generated by very different processes from the habitat loss patterns that (2) aims at describing. There are two general types of sampling for the SAR (Drakare *et al.*, 2006; Dengler, 2009): nested sampling and isolate sampling. In nested sampling, progressively larger areas of a continuous ecosystem are sampled, usually nested within each other (Figure 1(a)). The SARs generated by this type of sampling are also known as continental SARs (Rosenzweig, 1995), as in most cases they come from studies on continents. In isolate sampling (Figure 1(b)), habitat isolates with different area sizes are sampled. Initially, most of the SARs using isolate sampling came from island archipelagos, and therefore this type of SAR has been named the island SAR (Rosenzweig, 1995). A fundamental difference between nested and isolate SARs is that in nested SARs species number must always increase with the area size whereas in isolate SARs species number may increase or decrease with the area size.

The z -values of the SAR, key parameter to calculate extinction projections in [2], are often higher in oceanic islands than in nested areas in a continent. For instance, Rosenzweig (1995) gives a range of 0.25–0.35 for the former and 0.12–0.18 for the latter (Figure 2). However, recent studies have shown that the nested SAR exhibits a much broader range of z -values, from about 0.10 to more than 0.40 (Sala *et al.*, 2005; Drakare *et al.*, 2006), and that the z -values are particularly dependent on the scale of the study (Crawley and Harral, 2001; Pereira *et al.*, 2012). Furthermore, the z -value of isolates

Figure 1 The sampling scheme of the different types of species–area relationship: (a) nested sampling or continental SAR; (b) isolate sampling or island SAR.

on mainlands are often lower than the z -values of true islands in an ocean (Drakare *et al.*, 2006).

The species that are likely to go extinct immediately after habitat loss are the species endemic to the region of destroyed habitat (Kinzig and Harte, 2000; He and Hubbell, 2011). If the loss of the habitat happens in the periphery, then the nested SAR will describe the number of extinctions. This happens because the number of endemics in an outer ring of the habitat of size a is given by [2], assuming that the z -value of the SAR in [1] was estimated as in Figure 1(a) (Pereira *et al.*, 2012). If the habitat loss occurs in the center, the z -value from the nested SAR may overestimate the number of endemics. In that case, $z_{\text{isolate}} = 0.25$ the endemics–area relationship (EAR), built by counting the number of endemics in progressively larger areas (as in Figure 1(a)), will better describe immediate species extinction. The z -values of the EAR are generally lower than the z -values of the nested continental SAR (He and Hubbell, 2011).

Many species that were not confined to the areas of habitat loss may go extinct in the long term because the remaining area of habitat may not be sufficient to allow for their persistence (i.e., sink species, as their dynamics are dominated by the modified habitats in the landscape which act as sinks). The difference between the species that go immediately extinct and the species that are likely to go extinct in the future has been coined “extinction debt.” This second stage of extinctions can take from decades to millennia (Pereira *et al.*, 2010), and it has been proposed that it is better described by the island SAR

Figure 2 Comparison of the projections of species extinctions for the countryside SAR, the nested SAR and the isolate SAR. The EAR or the nested SAR (here $z_{\text{nested}}=0.15$) follow a similar shape, but with lower z -values than the isolate SAR (here $z_{\text{isolate}}=0.25$). Notice that when we use the classical SAR or the EAR all the species vanishes when the native habitat is completely lost. In the countryside SAR there are still species surviving when all the native habitat is converted. In this example we assumed that there are two groups of species (group 1 and 2) with the following parameters: $h_{1,\text{Native}}=1$, $h_{1,\text{Human-dominated}}=0.25$, $h_{2,\text{Native}}=1$, $h_{2,\text{Human-dominated}}=0.5$, $c_1=0.75$, $c_2=0.25$, and $z=0.25$.

(Rosenzweig, 2001). This happens because the island SAR is more the result of colonization/extinction dynamics than of the sampling effects that are intrinsic to the nested SAR and instantaneous extinctions. Note that another process, habitat turn-over, plays a role in both the isolate SAR and the nested SAR. SAR for multiple habitats, discussed in the next section, allows the study of the effects of habitat turn-over on extinction.

One problem with using the island SAR is that a fragment of native habitat surrounded by agricultural areas is ecologically different from an island surrounded by oceans: the agricultural matrix is more inhabitable than an ocean for most species. An alternative is to use the SAR from habitat isolates (e.g., in agricultural land) to estimate extinctions. A problem with this second approach is that, in many cases, time after fragmentation is still relatively short for the communities in sampled habitat isolates to have reached equilibrium. A third problem comes from the difference between what happens when a large region of native habitat is reduced and what are the processes determining species diversity in habitat isolates of different sizes in an agricultural matrix. In the latter, there can be source-sink dynamics between different patches while in the former the only source is the original habitat region; therefore, instead of a spatial source-sink dynamics we have a temporal source-sink dynamics. The problem is further compounded by the fact that the remaining habitat is likely to be itself fragmented.

Countryside Habitats: A Species–Area Relationship for Multiple Habitats

All of the SAR approaches described above assume that no species persist outside native habitats, and that when all

habitat is converted to human-dominated habitats (e.g., agricultural lands) all species go extinct (Figure 2). In reality many species are able to persist in human-dominated landscapes. For instance, at least half of terrestrial Costa Rican bird species and nonflying mammal species use agricultural habitats (Daily *et al.*, 2001, 2003). Pereira and Daily (2006) proposed a model to describe the use of both human-dominated and native habitats by many species: the countryside species–area relationship (countryside SAR).

The countryside SAR tracks the number of species in groups of species with similar affinities for the habitats in the landscape. The number of species in group i , S_i , is given by

$$S_i = c_i \left(\sum_{j=1}^n h_{ij} A_j \right)^{z_i} \quad [3]$$

where h_{ij} is the affinity of group i to habitat j , A_j is the area covered by habitat j , and n is the number of habitats. When the affinity of group i to the preferred habitat k is normalized to unity ($h_{ik}=1$), the habitat affinity h_{ij} becomes a conversion factor from the area of habitat j into an equivalent area of preferred habitat. The total number of species in the landscape is given by

$$S = \sum_{i=1}^m S_i \quad [4]$$

where m is the number of species groups considered.

The countryside SAR can be used to project the biodiversity response to scenarios of land-use change (Proença *et al.*, 2009). In contrast with the classic SAR, a proportion of species may remain in the landscape even if all native habitat is converted to human-dominated habitats (Figure 2). The countryside SAR suggests that neither the isolate SAR nor the nested SAR describes extinctions. Instead, the equilibrium number of species in a modified landscape is higher than what is predicted by either of these two curves. Extinction debt may occur, but it will be given by the difference between immediate extinctions caused by habitat conversion (the endemic species that cannot survive in the new habitat, which will be fewer than the ones projected by the EAR) and the species that will go extinct in the medium to long-term because they do not have enough source habitats (i.e., sink species). The countryside SAR is likely to describe the short-term extinctions better, but more research is needed.

The countryside SAR can be used to project biodiversity changes, not only from the loss of native habitat but also from an increase in native habitats, such as natural forests (Proença *et al.*, 2009), or other habitats such as forest plantations, as long as those habitats are incorporated into the model and the affinities of species for those habitats are calculable. The countryside SAR [3] has been compared with the classic SAR [1] in mosaic landscapes with multiple habitats, both at the local scale (e.g., $< \text{km}^2$, Proença *et al.*, 2009) and at the regional scale (e.g., 10^2 – 10^4 km^2 , Martins *et al.*, 2011). In both cases the countryside SAR performed better than the classic SAR in describing the number of species in a given area, although the improvement was specially marked at the local scale.

There have been other models proposed for a multihabitat SAR (Tjørve, 2002; Triantis *et al.*, 2003). The model from Triantis *et al.* (2003) substitutes area in the SAR by the product of the area with the number of habitats. Tjørve's (2002) model adds the SAR of each habitat in the landscape deducted by the number of species overlapping between habitats to produce an estimate of the overall species diversity. None of the models explicitly tracks groups of species with distinct habitat affinities.

Other Models

Here we discuss briefly three other classes of phenomenological models: direct inferences from geographic ranges, dose–response models and statistical estimators of diversity.

Global species distributions are now available for all terrestrial vertebrate groups (Mace *et al.*, 2005; Hoffmann *et al.*, 2010). Therefore, using the simple assumption that species are restricted to native habitats, the future range of a species can be estimated by obliterating from the species' current range all the areas that are projected to be converted to agriculture, according to spatially explicit scenarios of future land-use change (Jetz *et al.*, 2007). The declines in species ranges can then be classified according to the International Union for Conservation of Nature (IUCN) criteria to produce a list of future-threatened species (Jetz *et al.*, 2007). Projections that account for the persistence of species in human-dominated habitat can be obtained by classifying the suitability of the different land-uses for each species, and only obliterating from the current range of a species the area that will be occupied by habitat with no suitability for that species (Visconti *et al.*, 2011).

Dose–response models are based on correlations between the level of an ecosystem change driver and the biodiversity response. For instance, the GLOBIO model (Alkemade *et al.*, 2009) uses a matrix with estimates of changes in mean species abundances for conversions between any two types of land use, based on 89 empirical studies comparing species abundance between at least one land-use type and primary vegetation (Figure 3). Then, based on land-use change scenarios, GLOBIO projects changes in mean species abundance in each grid cell of the land-use maps, which can then be averaged over countries or regions. GLOBIO also uses relationships between the mean species abundance and other drivers such as the level of infrastructure development and the level of fragmentation, and assumes a multiplicative effect of the ecosystem change drivers to estimate the integrated impact on mean species abundance.

When sample plots are taken from a region, the total species diversity of the region can be estimated by using statistical estimators that use information on the number of plots in which each species was found. For instance, if the same species appear in all plots it is likely that all the species in the region were sampled. If most species occur in only one plot it is likely that many other rare species occur in the region and were not sampled, and therefore the species diversity of the region is higher than the number of species collected in the plots. Based on these statistical methods, Hughes *et al.* (2002) estimated the total number of bird species in a countryside region using samples from cattle pastures, coffee plots, mixed

Figure 3 Box and whisker plot of the mean abundance of species (MSA) relative to their abundance in undisturbed/primary ecosystems for several land-use categories. Reproduced from Alkemade R, van Oorschot M, Miles L, Nellemann C, Bakkenes M, and ten Brink B (2009) GLOBIO3: A framework to investigate options for reducing global terrestrial biodiversity loss. *Ecosystems* 12: 374–390, with permission from Springer.

agricultural plots, gardens, thin riparian strips of native vegetation, and small forest remnants. Then, in order to test the effect of the disappearance of certain elements from the landscape, they recalculated the diversity of the species in the region without the plots corresponding to those elements.

Process-Based Models

Reaction–Diffusion and Integro-Difference Equations

Reaction–diffusion models are spatially explicit models that track the population density of a species at each point in space. They were introduced in population ecology by Skellam (1951) and Kierstead and Slobodkin (1953), and are hereafter referred to as Skellam's equation (but sometimes also called the KISS model, after the name of these three authors). Earlier, reaction–diffusion had been introduced into population genetics by Fisher (1937), to look at the spatial spread of a mutant gene in a population. The main ingredients of Skellam's equation are the dispersal of individuals, which is approximated as a random diffusion process, and the local population growth dynamics (Shigesada and Kawasaki, 1997). For a population inhabiting habitat j , Skellam's equation is

$$\frac{\partial N(x,y,t)}{\partial t} = D_j \nabla^2 N(x,y,t) + F_j(N(x,y,t)) \quad [5]$$

where the symbol ∇^2 stands for $(\partial^2/\partial x^2 + \partial^2/\partial y^2)$, $N(x,y,t)$ is the density of the population, at location (x,y) at time t , D_j is the diffusion coefficient in habitat j and F_j is the growth rate function of the population in j and it can take distinct forms. If we assume, for example, that the population has logistic growth in habitat j with growth rate r_j and carrying capacity

K_j , then Skellam's equation becomes

$$\frac{\partial N(x,y,t)}{\partial t} = D_j \left(\frac{\partial^2 N(x,y,t)}{\partial x^2} + \frac{\partial^2 N(x,y,t)}{\partial y^2} \right) + r_j N(x,y,t) \left(1 - \frac{N(x,y,t)}{K_j} \right) \quad [6]$$

This equation allows for the simulation of source-sink dynamics (Pulliam, 1988) between different habitats in the landscape (Figure 4(b)): the source habitats correspond to habitats where $r_j > 0$ (i.e., the birth rate is higher than the death rate) and the sink habitats correspond to habitats where $r_j < 0$ (i.e., the birth rate is lower than the death rate). The model predicts that there is a minimum area of source habitat required to sustain a species in a human-modified landscape (Pereira *et al.*, 2004).

Skellam's equation is suited to describe the spatial and temporal evolution of a single species, but it can be generalized to communities of several species (Levin, 1974; Ökubo and Levin, 2001). For instance, Pereira *et al.* (2004) used Skellam's equation to study the response of the avifauna of Costa Rica to land-use change, and Pereira and Daily (2006) applied the same methodology to study the vulnerability of the mammal fauna of Central America in a countryside habitat. They applied Skellam's equation to each species individually using known population growth and diffusion coefficients from the literature or, when necessary, estimated them from allometric relationships. An important result of their work is that it is worth investing conservation resources in countryside habitats, in agreement with the results of the countryside SAR.

One of the advantage of Skellam's equation is its small number of parameters (at a minimum it involves three parameters: population growth rates in the source and sink habitats, and diffusion coefficient). In contrast, most models used in population viability analysis (Possingham *et al.*, 2001) tend to be very parameter rich, turning them difficult to apply to a community of species (but see Keith *et al.*, 2008). Still, Skellam's equation requires (and provides) more information than methods based on the SAR, because the latter assumes all

species to be equal (or in the case of the countryside SAR, all the species in a given group), therefore not taking into account their relative vulnerability to land-use change. Skellam's equation lies between the traditional (parameter poor) SAR and (parameter rich) population viability analyses.

There are, however, situations where the approximations implicit in Skellam's equation may not be reasonable, such as, when a species only reproduces and diffuses during specific periods of the year, or when diffusion coefficients are not appropriately modeled by normal distributions, such as when there are long distance dispersal events. In such cases, integro-difference equations are an alternative (Lewis, 1997; Hastings *et al.*, 2005). For a population in habitat j with density or number of individuals N , where r_j is the growth rate function and $k_j(x-x', y-y')$ is the dispersal probability between points (x', y') and (x, y) the integro-difference equation is

$$N_{t+1}(x,y) = \int_A k_j(x-x', y-y') r_j(N_t(x', y')) dx' dy' \quad [7]$$

where A is the area of habitat j and we kept t as a subscript to highlight the discrete temporal nature of the equation. Naturally, like Skellam's equation, integro-difference equations can also be applied to entire species communities, but so far we are not aware of such applications to countryside habitats.

Multispecies Metapopulation Analysis

Like Skellam's equation, metapopulation analysis was originally developed to study only one species. Levins (1969, 1970) developed the basic framework that was later considerably developed by authors such as Ilka Hanski (e.g., Hanski, 1999). The main idea of metapopulation analysis is to consider several populations of the same species inhabiting several patches, which are interconnected through dispersal, and determine how many patches are occupied at one time (Figure 4(a)). If the rates of colonization and extinction are c and e , respectively, and the fraction of occupied patches is given by P then the equation governing the time evolution of the fraction of occupied patches is

$$\frac{dP}{dt} = cP(1-P) - eP \quad [8]$$

If $c-e > 0$, the fraction of occupied patches reaches an equilibrium, $P^* = (1-e/c)$. Naturally, this basic model can be refined. For instance, e and c can depend on the number of occupied patches, one can take into account the size of the patches and their explicit location, or one can consider patches of different "quality."

The metapopulation approach has definitely an appeal for studying countryside landscapes, because habitat loss and disturbance leads to populations inhabiting interconnected fragments, therefore following closely the premises of the metapopulation's theory framework. For example, Kuemmerle *et al.* (2011) used a metapopulation model to assess different strategies to establish (meta) populations of the European bison (*Bison bonasus*) in the Carpathians. However, in contrast with Skellam's model presented in the previous section, it assumes that the matrix (e.g., agricultural land) is only used for dispersal (Figure 4(a)). Notice that Skellam's model allows for the matrix to be used as sink habitat, and therefore tracks

Figure 4 Schematic representation of a metapopulation (a) and of the source-sink dynamics of the Skellam model (b). (a) The population occurs in the green patches, and each patch has a colonization rate (dependent on the distance to other patches) and an extinction rate (dependent on the size of the patch). (b) The population uses the entire landscape, but has a different fitness in each habitat. In a source habitat (green patches) birth rate is greater than mortality rate, while the reverse happens in the sink habitat (white matrix). The former case leads to dispersal ability being a positive factor to the survival of the population because more patches can be colonized. In the latter case dispersal may be detrimental because more individuals reach the sink habitat.

the source-sink dynamics of populations across the entire landscape (Figure 4(b)).

Another important difference between source-sink models and metapopulation models concerns the impact of dispersal ability. While in metapopulation analyses the role of dispersal is beneficial because individuals can colonize more patches, in reaction-diffusion models dispersal affects the population negatively because individuals tend to disperse away from good patches to sink habitats where population growth rates are negative (e.g., Borda-de-Água *et al.*, 2011). This disparity arises because the source-sink dynamics of Skellam's model are deterministic and the metapopulation models are stochastic. In a stochastic environment it may be advantageous to disperse to spread the risk between different patches, while in a deterministic environment dispersal is costly and tends to be disadvantageous (but see Hamilton and May, 1977 for a competitive benefit of dispersing individuals in a deterministic environment).

How do the relative costs and benefits of dispersal play out in fragmented landscapes or countryside habitats? Unfortunately, most metapopulation models ignore the population costs of dispersal and are unable to answer this question. Casagrandi and Gatto (1999) tackled this issue by developing a stochastic model that takes into account the number of individuals in each patch and, importantly, that takes into account dispersal mortality or inability to colonize. They show that only when dispersal rates are very small does the probability of persistence of the metapopulation increase, otherwise, the probability of extinction increases when dispersal increases (Figure 5).

Figure 5 Population persistence (white area) as a function of the intrinsic rate of increase (y -axis) and dispersal rate (x -axis). When dispersal increases then the region of parameters where deterministic extinction occurs increases as well (dark-gray area). However for very small values of the dispersal rate ($D < 0.25$) extinctions caused by demographic stochasticity decrease when the dispersal rate increases (light gray area). Reproduced from Casagrandi R and Gatto M (1999) A mesoscale approach to extinction risk in fragmented habitats. *Nature* 400: 560–562, with permission from Nature.

Most metapopulation studies focus on a single species, but metapopulation models have also been applied to communities of species (Nee and May, 1992; Tilman *et al.*, 1994; Marvier *et al.*, 2004). For example, Tilman *et al.* (1994) used a multispecies model to study the extinction debt in a fragmented landscape, and concluded that the most abundant species in an undisturbed habitat can be the most susceptible to extinction after habitat destruction. This happened because in their model there was a trade-off between being best competitor and best colonizer; hence, if fragmentation affects colonization, the species that had previously been the best competitors, and so the most abundant, became the most affected because of limitations to dispersal due to fragmentation. More recently, Keith *et al.* (2008) have integrated metapopulation models with bioclimatic envelope models to look at the response of a community of 234 plant species of the South African fynbos to climate change. They used age/stage-based matrix models to track the population size in each patch, and incorporated density dependence, environmental, and demographic stochasticity in the model, using the software RAMAS GIS (Akçakaya, 2000). A similar approach could be used to model the biodiversity dynamics of land-use change, where the bioclimatic envelope models and associated climate scenarios would be replaced by habitat suitability models applied to land-use change scenarios.

Neutral Theory

While source-sink and metapopulation models were originally developed to study one species at the time, the neutral theory of biodiversity and biogeography (Hubbell, 2001) has at its core the relative abundance of species within a community. By “neutral” it is meant that all species in the same trophic level have the same probability of dying, reproducing, and speciating. Such an approximation has proved very controversial among ecologists (McGill, 2003; Clark, 2009), but the theory has inspired many recent studies in theoretical and applied ecology (for a review see Rosindell *et al.*, 2011). We should also point out that the classic Theory of Island Biogeography (MacArthur and Wilson, 1967) is also neutral because it assumes that all species are equal in their ability of dispersal, colonizing, and becoming extinct. An important difference, however, is that the Theory of Island Biogeography assumes neutrality at the species level, while neutral theory does it at the individual level and, as a consequence, the Theory of Island Biogeography can deal with species richness but not relative abundance.

In the original version laid out by Hubbell (2001), neutral theory considered two different scales: the local community corresponding to the local scale (e.g., the trees of a 50 ha plot of tropical rain forest), and the metacommunity corresponding to the regional scale (such as the Amazon basin). At both scales death and birth are part of the model, but while in the metacommunity speciation is the driving force providing new species (and, in the process, avoiding community dominance by a single species), in the local community that role is provided by migration of individuals from the metacommunity. According to the neutral theory model, at each time step an individual dies and is replaced with a new one. When

dealing with the local community, the new individual can be from a local species or an immigrant from one of the species in the metacommunity (that may or may not be present in the local community). The important characteristic of the theory is that all the processes are function of the species relative abundances; for example, if there is a migration event, the probability of choosing a species from the metacommunity is proportional to its abundance there. The evolution of the meta and local communities leads to the number of species and their relative abundance to reach an equilibrium value, characterized by the speciation and migration rates. This, however, is a dynamic equilibrium because species abundances drift over time; therefore, the species composition may change. It is only the number of species and their relative abundance that remain approximately constant.

Halley and Iwasa (2011) used a simplified version of neutral theory, by ignoring the immigration term, to estimate the time for accruing extinction debt in an isolated fragment. Under their model they derived the following diffusion equation:

$$\frac{\partial p}{\partial t} = \sum_{i=1}^{S-1} \frac{\partial^2}{\partial x_i^2} \left(\frac{x_i(1-x_i)}{N\tau} p \right) - \sum_{i=1}^{S-1} \sum_{j>i} \frac{\partial^2}{\partial x_i \partial x_j} \left(\frac{2x_i x_j}{N\tau} p \right) \quad [9]$$

where S is the number of species in the community, N the number of individuals in the habitat fragment, τ is the mean generation time, x_i is the relative abundance of species i , and $p(x_1, x_2, x_3, \dots, x_{S-1})$ is the distribution of the relative abundances for up to the last species, whose relative abundance is $x_S = 1 - x_1 - x_2 - x_3 \dots - x_{S-1}$. From this equation, they calculated the analytical expression for the time it takes for the number of species to reach half of its original size, S_0 , as $t_{50} = \tau N / S_0$. The decay over time of the number of species is given by

$$S(t) = \frac{S_0}{1 + t/t_{50}} \quad [10]$$

Halley and Iwasa found very good agreement between their model and published empirical results for avifauna relaxation in fragments of intermediate size (100–100,000 ha), but noticed that the model broke down either for very small or very large areas, and hypothesized that this breakdown was due to the lack of immigration and speciation in their model.

Other studies have applied neutral models to estimate the number of tree species extinctions in the Amazon Basin for spatially explicit deforestation scenarios (Hubbell *et al.*, 2008), and to predict the rate of extinction of tree species in isolated fragments of the Amazon forest (Gilbert *et al.*, 2006).

Concluding Remarks

There is now a wide range of models available to look at biodiversity dynamics on countryside landscapes. Process-based models require more parameters than phenomenological models, and therefore they have been mostly applied to local scales and to a single species or a small set of species. In contrast, phenomenological models may require as little as one parameter, and they have been applied to projecting

changes at global to regional scales for the total number of species. However, phenomenological models have also been used at the landscape scale, and there have been attempts to generalize and upscale the projections of process-based models. The type of projections needed (e.g., individual species vs. species groups, time to extinction vs. number of extinctions) and the data available are the key factors in determining the most appropriate model.

Paleoecology

Thompson Webb, Brown University, RI, USA

© 2013 Elsevier Inc. All rights reserved.

Glossary

AMS dates Radiocarbon dates obtained by directly measuring the amount of carbon 14 in a sample by using an accelerator mass spectrometer.

Bryophytes Mosses and liverworts; nonvascular plants.

Cyperaceae Sedge family.

Fagus grandifolia American beech trees.

Late Quaternary The past 21,000 years since the last time of maximum glaciation.

Palynology The study of pollen and spores.

Pliocene The period of geological time from 3.5 to 1.8 Ma.

Quaternary The past 1.8 My of geological time.

Radiocarbon dates Dates of organic matter in geological samples using the radioactive decay of carbon 14, which has a half-life of 5750 years.

Tracheophytes Vascular plants.

Introduction

Past ecosystems are a continuous creation of those who study them. What is mapped through time or reduced to time series depends on the data available and the training of those who interpret and display the data. Studies in paleoecology, therefore, are an exercise in perception and interpretation that depend, to some extent, on the sensitivity of the data in time, space, and taxonomy. The ultimate goal is to understand what occurred ecologically in the past, but this understanding can only be obtained if reliable records exist of past taxon distributions (or other components of ecosystems) that can be displayed and interpreted in informative ways. Simple time series are not enough because of the many spatial variations and processes that affect the temporal changes at a site. Geographic networks of temporally varying data are required to show how past and present taxa have varied in abundance, location, and association within and among their associated ecosystems.

The focus here is on the rich data sets of Quaternary pollen and plant macrofossils that provide records of the major changes in vegetation at a variety of space and timescales. These data (*see* Neotoma Paleoecology Database – <http://www.neotomadb.org/>) provide a valuable bridge between modern ecological data and the fossil evidence in the Paleobiology Database, which paleontologists are compiling. The Quaternary data sets yield a remotely sensed view of past vegetation, landscapes, taxon migrations, and invasions and illustrate various temporal changes in ecological assemblages and communities (Huntley and Birks, 1983; Williams *et al.*, 2004; Binney *et al.*, 2009) – all of which show changes and patterns in biodiversity. Direct measurement of the changing

numbers of species through time, however, is not always possible with pollen data, even when supplemented by plant macrofossil data, although the extinction and arrival of some species are evident in records dating back to the Pliocene (Hoogheemstra and Ran, 1994). The focus with these paleoecological data, therefore, is on vegetation and its diverse changing patterns of composition and distribution through time and space and how environmental factors, such as climate, disease, fire, and human activities, have influenced these changes. Other types of data such as ground-penetrating radar records, sediment characteristics, diatoms, ostracodes, and various geochemical measures allow independent interpretations of past environmental changes and thus permit the pollen and plant macrofossil data to show the taxon-level and vegetational response to these past environmental changes (Shuman *et al.*, 2002, 2004). The combinations of data sets illustrate the ecological and environmental setting within which modern patterns of biodiversity have arisen. They also demonstrate, as long claimed by Richard West and Margaret Davis, that the “present plant communities have no long history.”

Data and Sensing System

Just as satellite-derived vegetation data today can be displayed in time series of maps, the pollen and plant macrofossil data can be viewed as if they came from a video recorder from high in space with resolution in places of up to 10 m. The images that are retrieved can be of high or low resolution temporally, spatially, taxonomically, and numerically, and they can illustrate local to global changes in plant populations, vegetation,

biodiversity, human activity, fire frequency, and plant diseases over decades to millions of years. Because each of these entities or phenomena varies spatially and temporally, records of data covering a breadth of scales in space and time are needed. To obtain the highest quality images of a specific phenomenon requires an understanding of the sensing system that accumulated the data. How does the paleoecological video-recording system work and what are the scaling characteristics of the images that it registers? These characteristics include breadth of coverage, sampling resolution, and sampling density in time, space, and taxonomy. Studies of pollen and plant macrofossil data covering a variety of temporal and spatial scales within the Quaternary have helped provide this understanding.

Quaternary paleovegetation data pose several problems for interpretation. The main problem arises because pollen samples in sediments represent death assemblages of immature microgametophytes (i.e., pollen grains) that differ manifestly from the assemblages of sporophytes (i.e., plants) that produced the pollen. Studies of modern data from surface sediments have therefore focused on identifying the features of plant assemblages that appear in pollen records. This work parallels ground-truthing studies by scientists deciphering the remotely sensed data from satellites because pollen data are a form of remotely sensed data from plant populations and vegetation. Just as the current vegetation emits or reflects radiation that remote sensors on satellites intercept, so too does (and has) the current (and past) vegetation shed pollen that accumulates remotely (i.e., well away from the source) in lakes and bogs. Both types of remote sensors (satellite instruments and lake sediments) record data with certain sampling characteristics (e.g., spatial and temporal resolution), and their data need calibration and ground-truthing in terms of vegetation attributes such as composition (taxon abundances), structure (height and mixture of growth forms), and pattern (geographic gradients and mosaics and aspect of beta and gamma diversity). Studies of spatial arrays of modern data by Bradshaw, Prentice, Hicks, Calcote, and Jackson have provided this calibration and ground-truthing.

Down-core studies of pollen bring time into the picture, and temporal resolution becomes one of the factors controlling what is recorded in the data. Pollen in annually laminated sediments can provide seasonally distinct samples as neatly shown by Peglar *et al.* (1984), but most samples integrate 10 or more years and can be independently dated back 40,000 years with an average precision of ± 200 years for data from within the past 12,000 years. However, if vegetational and ecological phenomena are the target for study, then spatially distributed data are needed because vegetation and biodiversity are inherently spatial entities that vary on virtually all time and space scales. Recording their full dynamics requires time series of geographically distributed data that yield a zoom lens space-time perspective. The author focuses on how the different scaling characteristics of the data sets control what we see and on how data can be organized to yield such a zoom lens perspective. The author discusses each of the sampling characteristics in taxonomy, space, and time. The author then describes different ways to display and visualize the data and some of the vegetational dynamics that they have revealed.

Scaling Factors

Most Quaternary palynologists obtain their data from sediments from lakes, mires, or estuaries where (1) sediments and pollen grains accumulate relatively continuously, (2) the sediments are organic enough for radiometric dating, and (3) the pollen data blow or wash in from the surrounding vegetation. In these sediments, pollen grains are morphologically distinct and numerous, and plant macrofossils are often found. (Pollen and plant macrofossil data are also available from deposits that are discontinuous in time but can be organized into time series; Baker *et al.*, 2002; Betancourt *et al.*, 1990). Once analyzed, the data exist as point estimates of the abundance for each taxon in time series of samples at a site (or at nearby sites and middens for some discontinuous records). These time series can be expanded to transects of time series in latitude-, longitude-, or elevation-time diagrams, to networks of samples from an area for mapping, or to networks of time series, which are also time series of maps, to form a space-time box for displaying the data (Figure 1). Each of these displays illustrates different views in different dimensions of the space-time variations in the data. A zoom lens perspective can then be achieved in space, time, or both simultaneously by moving from data at a single site for a short time interval to progressively longer time series for either that site or for data on maps from increasingly larger areas. In this way, records of local succession can be seen in the broader context of long-term migrations and global climate changes.

Palynologists control the ability of their data to display selected patterns in vegetation and biodiversity (both in time and in space) by making choices about the numerical aspects of their data and by choosing the temporal, spatial, and taxonomic sampling characteristics of their data. These sampling characteristics have three elements – breadth of coverage, resolution of individual samples, and sampling density – which for a photograph are comparable to its frame of reference, grain size, and number of grains (or pixels) that are exposed, respectively. The temporal and spatial breadth of the data is the total time or area covered by a data set, and the taxonomic breadth is the total set of taxonomic groups (e.g., seed plants) included. The temporal and spatial resolution of each sample is defined in terms of how much time or area is represented in each individual sample within the data set, and taxonomic resolution depends on whether the data are lumped into groups or listed at their finest level of morphological distinction. The uncertainties of radiocarbon dates and age estimates also affect temporal resolution in correlations among sites. The number of samples in time and space defines the temporal and spatial sampling density. The total number of taxa listed in a data set defines the taxonomic sampling density. Choices about these characteristics can influence what types of changes in vegetation and biodiversity appear in paleoecological times series and map sequences (Figures 1–3).

Taxonomic and Numerical Characteristics

In most studies of lakes and bog sediments, the potential taxonomic breadth is Tracheophytes and Bryophytes along

Figure 1 Pollen data in time and space. Different views from time series for multiple taxa at a single site to a single taxon (spruce) displayed either for a transect of sites in a latitude–time diagram or for a network of sites in the time series of maps from 21 k Cal yr (thousands of calendar years ago) to present. The shading on the maps indicates pollen abundances of 1–5% (light gray) and >5% (black). The white area at the top of the maps for 21, 18, 14, and 10 ka is the Laurentide ice sheet. When stacked vertically, these maps form a space–time box in which the three-dimensional contours can show the four-dimensional distribution of spruce pollen percentages in space–time.

with certain algal remains (*Pediastrum*) and fungal spores. When nonwetland vegetation is a primary focus, spores, algal remains, and pollen and plant macrofossils from aquatic plants are excluded from detailed study. Careful study and morphological characteristics of pollen grains determine the taxonomic resolution in samples and permit identification of genera and some species, although some grains can only be determined to the family level (e.g., Poaceae and Cyperaceae). Regional restriction of a single species, otherwise morphologically identifiable pollen only at the genus level (e.g., *Fagus grandifolia* within the northeastern US), can allow designation

of plant species from pollen, but plant macrofossils, if present, allow species to be identified directly.

Palynology is a direct beneficiary of the ubiquity and inefficiency of wind pollination. Millions of grains are produced for every successful pollination, and some of the abundant residual reaches the sediments of lakes and bogs where the pollen grains are well preserved. Entomophilous grains are abundant in honey and on the legs of bees, but too few insects perish in lakes and bogs to leave a record that can be discerned among the overwhelming numbers of anemophilous grains. From the point of view of the remote-sensing metaphor,

Figure 2 Zoom lens view of the mapped distributions of oak tree and pollen percentages at the scales of a subcontinent (107 km^2), state (105 km^2), and county (103 km^2). These maps show how well pollen percentages can reflect the distribution of tree percentages. Data used in contouring at the subcontinental scale were also used in contouring at the state scale, but a different data set was used at the county scale. Modified from Solomon and Webb (1985).

wind-pollinated plants are bright lights on the landscape and little or no signal comes from the other plants. As a result of this bias, the focus is on using pollen data to record the vegetation rather than species lists. For temperate to boreal forests in which the diversity of wind-pollinated trees is greatest globally, pollen records provide a fairly direct representation of the vegetation; however, in tropical regions and deserts, the pollen records yield a much more indirect representation of the vegetation because so many species are insect-pollinated.

In arid lands of southwestern North America, where lakes are rare, packrats create middens with embedded plant macrofossils that can be radiocarbon dated and identified to the species level for those plants collected (Betancourt, 2004). These records provide valuable information about arid vegetation and environments including studies of Holocene plant migration and biogeography (Lyford *et al.*, 2004; Gray *et al.*, 2006).

In most studies of Quaternary pollen, taxon percentages are used. Three hundred to five hundred grains are typically counted in a sample, and the counts for each taxon are divided by the total count. Because counts for individual taxa can be thought of as being binomially distributed (i.e., each grain is either taxon x or not taxon x), the percentages for multiple taxa are multinomially distributed, thus permitting direct calculation of confidence intervals. Pollen concentrations (grains cm^{-3} or grains g^{-1}) are seldom used because of their dependence on sedimentation rates. When radiocarbon or stratigraphic dates allow estimation of sedimentation rates, pollen accumulation rates ($\text{grains cm}^{-2} \text{ year}^{-1}$) can be calculated, and procedures exist for calculating and potentially minimizing the confidence intervals for both pollen concentrations and accumulation rates.

Pollen accumulation rates, first introduced by Margaret Davis, have proven valuable for checking the ambiguity of

Figure 3 Zoom lens view of the vegetation from the scale of single site (where pollen accumulates) up to the global scale. No one view or interpretation of the vegetation is possible because the composition and gradients vary with scale and reflect climate gradients at the global and continental scales, a mixture of soil and climate gradients at the regional scale, and difference in soils and disturbance history at the landscape and local scales. Modified from Kutzbach and Webb (1991).

certain changes in pollen percentages. However, pollen accumulation rates are unsuitable when large sets of comparably sampled pollen data are required for mapping. These rates are highly sensitive to sedimentation differences within and between lakes as shown by Pennington and Davis and thus vary dramatically for nonvegetational reasons. Percentages of pollen taxa, which serve to cancel out these variations, are therefore best used in mapping studies (Figures 1–3). Many studies show that the percentages for pollen taxa represent well the relative abundance of plants on the landscape. The relationships vary with spatial scale and pollen type, and the uncertainties of these relationships add to the number of uncertainties for the pollen data when estimates of the vegetation are attempted.

Finding reliable quantitative measures for plant macrofossils is much more difficult than for pollen data. Most data

are recorded in presence/absence terms or categorically, but sometimes percentages or concentrations are calculated. Local biases can make the data difficult to interpret because, for example, 1000 needles may all come from the same nearby tree.

Spatial Characteristics

The breadth of coverage for sets of pollen data can be broad or fine and thus match the different scales for mapping the vegetation (Figure 3). Continental and global data sets exist (Prentice *et al.*, 2000) along with those at regional (1000–300,000 km²) and local (10^{−3} km²) scales, and an embedded series of these data sets can provide a zoom lens view of past vegetation change if the sample resolution and sampling density are appropriate.

The potential spatial resolution of individual pollen samples varies among pollen taxa depending on the dispersibility of their pollen. Pollen from taxa with large grains is dispersed less far than that with small grains. Individual pollen samples are therefore variable-area samples, with the area of vegetation contributing pollen depending on which pollen type is studied; the percentages for pine pollen, for example, represent a larger area than those for beech or maple. Such differences in sampling area among pollen types can be important for studies of local or even regional vegetation but are less important for networks of data in which the distance between samples is much larger than the average dispersal distances for the different taxa.

The potential spatial resolution also depends on the basin characteristics. Key factors include the presence or absence of a canopy over the basin, the size of the water or wetland surface accumulating airborne pollen, the presence or absence of horizontal mixing of sediments within the basin, and the watershed area that supplies additional waterborne pollen to lakes. Samples from within a forest canopy accumulate most of their pollen from plants growing with 10–100 m of the coring site, and data from samples that preserve pollen are comparable spatially to vegetation data from large permanent plots in forests. In contrast, samples from lakes accumulate their pollen from distances of 100 m to 30 km. The within-canopy data have enough spatial resolution to illustrate succession within forests (Figure 4), whereas pollen data from lakes integrate across the mosaic of vegetation on landscapes and are sensitive to succession only if it is occurring across much of the pollen-source area. Bogs, mires, and shallow wetlands accumulate pollen at both regional (1 to > 10 km) and local (10 m) scales because many plants grow on these wetlands. In samples within mires, pollen from local taxa can vary systematically and abruptly, whereas the pollen from regional taxa remains reasonably uniform. (This behavior of pollen percentages for regional taxa led von Post to develop pollen analysis as a method in 1916.) The spatial resolution of pollen samples, therefore, varies with pollen type within certain basin types, but selection of samples by pollen type and basin type can help keep the spatial resolution reasonably uniform. Such choices are key to seeing well with the observations afforded by sets of pollen samples.

For plant macrofossils, Dunwiddie and Jackson have shown that needles and seeds in lake sediments have a spatial sampling resolution of 10–20 m, which is much finer than the distance sampled by most pollen in lakes or open wetlands. Plant macrofossils can therefore help resolve local changes at or near a site and fine-scale elevation differences (Jackson and Whitehead, 1991). Sampling schemes can use a mixture of open and canopy-covered basins, mire and lake sediments, local and regional pollen types, and plant macrofossils in order to represent different scales of spatial pattern in the vegetation. Such mixtures of data sets can show vegetation differences that reflect specific soil and elevation differences within a broader geographic data set. Mapping of plant macrofossils can also show the range of species and of haplotypes and add precision to what maps of pollen data show (Jackson *et al.*, 1997; Binney *et al.*, 2009; Magri *et al.*, 2006).

The geographical sampling density for pollen data varies. To illustrate the variations in recent pollen within a basin or a forest, some studies include samples at 10 m or finer intervals along 500 m or longer transects through a basin or forest. For selected taxa, these studies show high sensitivity in the pollen data to local variations in vegetation cover and biodiversity. The variations are also evident in sets of time series from closely spaced cores in a basin (Simmons, 1993). For studies whose breadth of coverage is regions to continents (Figure 3), sets of modern data exist with average densities of 1/14 km² in 1000 km², 1/500 km² in 100,000 km², and 1/5000 km² in 107 km². These densities are sufficient for the contour patterns of oak pollen percentages to match the corresponding patterns of oak tree percentages at each spatial scale (Figure 2). Sets of fossil data provide less dense geographic coverage and vary in density from 1/50 km² for the Adirondacks to 1/6000 km² for the northern Midwest and 1/40,000 km² for eastern North America and Europe (Gaudreau *et al.*, 1989; Williams *et al.*, 2004).

These data sets have been used to illustrate how well pollen data represent or remotely sense spatial vegetational features such as range boundaries, ecotones, and abundance gradients (Figures 2 and 3) (Williams *et al.*, 2004; <http://www.ncdc.noaa.gov/paleo/pollen/viewer/webviewer.html>). Detecting the range boundary with pollen can be difficult because of pollen transport and relatively high counting uncertainties at low pollen percentages, but Davis *et al.* (1991) used a data set from the Midwest with a sampling density of one sample per 1000 km² to show that the past species limit for beech and hemlock can be identified within an area 20 km wide. For widely dispersed taxa such as oak and pine, such fine-scale resolution may not be possible, but the abundance gradients for these taxa can be used to locate ecotones at scales of 10–100 km (Figure 2).

Temporal Characteristics

The time range for records from individual cores can vary from 50 years to millions of years ago (Figure 4), with the bulk of the late Quaternary cores covering 14,000 years and fewer extending back 21,000 years, the last glacial maximum. Temporal density generally correlates with time range because short cores are often taken to study short-term changes and may contain 10–20 samples for 500 years, which yields one sample per 25–50 years, whereas 200 samples in a 2-million-year (My) record can only yield one sample per 20,000 years. Twenty to 40 samples for 10,000 years yield one sample per 250–500 years, which is typical for most cores in the data sets from eastern North American and European (Huntley and Webb, 1988). At a high level of temporal density are records from millimeter-scale sampling of peats that have yielded 1- to 5-year sampling for 50–200 years for selected times in the past, as reviewed by Turner and Peglar (1988) and Simmons (1993).

One of the longest continuous records for the Quaternary is from Sabana de Bogota in Colombia and covers 1.5 My (Figure 4). This study is remarkable in having relatively high sampling density of one sample per 1000 years and shows the appearance from North America of *Alnus* and *Quercus* at 1.3

Figure 4 Zoom lens view of pollen data in time from a 1.5-My record down to a 300-year record. Different ecological processes are evident on different timescales. Temporal coverage, resolution, and density all vary appropriately for the Colombian lake record of alder pollen to show (a) alder's arrival at the site long after North and South America joined and (b) its response to orbitally driven climate changes (Hoogheemstra and Ran, 1994). The California lake record of oak pollen shows its response to orbitally driven climate variations over 130,000 years and the transition from glacial to interglacial climate over 16,000 years. In Wisconsin, pollen data from a lake that is free from bottom-organism mixing are sufficiently high in resolution to record how oak and pine populations responded to climate and regional disturbance events (e.g., fire) over 11,000 and 2500 years, respectively. Local succession is evident in the pollen data from a 300-year record from a small hollow within the forest canopy in Massachusetts (Foster and Zebryk, 1993). Gray indicates a portion of a time series that is expanded in the graph on the right.

million and 250,000 years ago, respectively. Other long cores with records of 50,000 years or longer exist on all continents but Antarctica; however, only in Europe are these long cores numerous enough to allow some mapping of vegetation from previous glacial and interglacial periods.

At the other extreme in terms of temporal coverage are (1) short cores of the upper sediments of lakes or bogs and (2) cores from forest soils that preserve pollen. The former provide records of human impact on the vegetation and of recent changes, whereas the latter show combined fine-scale sampling in both time and space and provide the view most closely approximating scale within which succession into forest gaps occurs. One of the ironies of paleoecological research is how seldom the data reveal succession as the dominant dynamic in the vegetation even though much ecological research has focused on succession.

These short-term records are often analyzed in high temporal density, for example, one sample per 50 years or even one per decade. The short cores (50 cm to 2 m) from lakes give coverage in high detail for 100–500 years or more in transects or in networks of relatively high spatial density (one sample per 1000 km²) from states or regions (Russell *et al.*, 1993; Foster and Aber, 2006). Dating can be fairly accurate and precise because historical dates can be assigned to events in cores, and the date for the core top is usually known. High-resolution mapping in 50-year intervals is possible.

Temporal Resolution

A key metaphor for thinking about temporal resolution within individual samples and cores is to consider stratigraphic sections of lake sediments as strip charts along which pollen data have accumulated to form palygraphs. The sediment accumulation rate (which varies but averages 0.7 mm per year in most Holocene lakes) measures the drum speed (as on a thermograph) that drives the strip chart past the recorder, and the mixing of sediments between one and a few cm of the sediment surface after burial measures the degree to which the pen recording the data wiggles up and down vertically in time while registering horizontally the changing abundances of pollen. Within this sediment mixing zone, older sediments are moved both up from below (2–6 cm) and in from other parts of the basin by reworking. Such processes can make for tricky pen work on the palygraph. If the paper in the imagined palygraph were to absorb the ink slowly such that the scatter of tracings in the upper mixed zone is reduced to a single tracing of the abundances below this zone, then our metaphorical instrument would yield what is finally observed downcore. This image of the palygraph helps by indicating the separate components controlling temporal resolution in a core. The mixing depth and sedimentation rate largely control postdepositional time averaging, which regulates the time interval (i.e., temporal resolution) represented by pollen in a sample, whereas the temporal density of samples recorded and the accuracy and precision of assigning dates to each of many cores (strip charts) control analytical time averaging, which determines the temporal resolution among a set of cores used for mapping.

Dating Uncertainties

The dating uncertainty of an arbitrary pollen sample at some depth in a core depends on the uncertainties of the dating method, what is dated, the uncertainties of the age model, and variations in the sediment accumulation rate. The most accurate and precise dates are from lakes with annually laminated sediments, whose annual layers can be counted. These dates are in calendar years and accurate, with dating errors of only 1% or 2% at most. Unfortunately, lakes with such precision are too sparsely distributed for detailed mapping work. For lakes without varves, the dating near the tops of cores is more accurate and precise than that lower in the core because historical dates can be assigned to events in the core. These dates have uncertainties of 50 years or less and can be pinpointed in the core to 1 or 2 cm.

In studies of Late Quaternary data, most cores have been dated by conventional radiocarbon dates of bulk sediments. The bulk dates give the dates for the sediment matrix (i.e., strip chart material) and not for the pollen embedded within the sediments (i.e., what the pen records). The bulk dates have counting uncertainties of 20–400 years, with most approximately 100 years. These average errors give ± 200 years as the 95% confidence interval for each date. The dates can also be derived from 2 to 10 cm of sediment and therefore may average sediments covering 20–1000 years in age depending on the sediment accumulation rate. When dates for synchronous pollen events are averaged, such as the elm decline in Europe and the hemlock decline in eastern North America, standard deviations of ca. 300 years result. This uncertainty incorporates both the depth and the counting uncertainties. As Olsson (1986) observed, “There is ... no point in determining the radiocarbon age with an uncertainty of ± 50 years if the relevant pollen-analytical level has an uncertainty of ± 200 years.”

Olsson (1986) and Grimm *et al.* (2009) also note the problems with contamination, old carbon, and sampling depths. Old carbon can lead to systematic errors of 2000 or more years and requires correction. Dates on wood and accelerator mass spectrometer (AMS) dates on macrofossils in cores are helping to reduce these errors, and AMS radiocarbon dates are allowing depth intervals of 1 cm or less to be dated. Pilcher (1993) concludes that standard errors for radiocarbon dates from sediments are potentially ± 200 years but not more than ± 225 years. Recent work using many AMS radiocarbon dates on selected macrofossils and wiggle matching can lower this uncertainty however, and holds much promise for studying century-scale phenomena (see Hormes *et al.*, 2009).

Age Models and Mapping Intervals

Most pollen samples (30–50 per core) are not dated directly by a radiocarbon date (3–6 per core). Rather, their age is estimated by an age model based on linear interpretation, regression, or some other curve-fitting method. For cores with continuous sedimentation, the age model estimates the drum speed for the strip chart on the palygraph.

The uncertainties for all data plotted on the map for 12,000 years ago give an estimate for the amount of time before and after 12,000 years ago that the pollen data may cover on the

map. The uncertainties are likely to be between 300 and 500 years. This dating uncertainty for the data mapped matches the average temporal sampling density of one sample per 300–500 years in Late Quaternary pollen studies. Given such large uncertainties, maps to-date are best restricted to 1000-year intervals. Attempts to map at finer intervals will only produce maps whose data are not independently observed from the data in the maps for the next earlier and later dates.

As more studies get done at higher temporal resolution and with greater sampling interval, mapping can be attempted at finer time intervals. For sets of short cores in which historical dates yield a precision of 50 years or less, age models back to 500 years can yield dating sufficiently precise for maps in 100- to 50-year intervals. For regions over which stratigraphic markers such as volcanic ash represent synchronous layers in cores, some fine-scale mapping intervals are possible for the distant past, but even the dating of tephra has uncertainties of a century or more. Pollen-assemblage zones are sometimes used chronostratigraphically and can yield temporal resolution to 50 years or less among nearby cores, but synchronicity must be assumed for processes (e.g., abundances changes for individual taxa) that are ultimately time transgressive, especially at scales of 200 km or more. The geographic area for maps at a fine time resolution is therefore relatively small, but may be enlarged as more studies like that by *Hormes et al.* (2009) are completed.

Zoom Lens Perspective

Time series and mapped networks of pollen and plant macrofossils record Late Quaternary vegetation patterns at the scale of local vegetation, landscapes, regions, and continents (Figures 1–4). A hierarchy of nested data sets can reveal vegetation patterns at a variety of scales and provide information from general to detailed about the spatial vegetation patterns (Figures 2 and 3). Such hierarchies can link local changes to global events by recording each simultaneously (Kutzbach and Webb, 1991). A paleoecological zoom lens can then be used to examine the vegetation patterns that dominate different spatial scales for areas of 100–10⁷ km² with a spatial resolution of 10⁻²–10⁴ km over timescales covering 10–10⁴ years (with time series to 10⁶ years) with resolution from 1 to 500 years (Figure 4). From a global perspective over thousands of years with a relatively coarse grid of temporally and spatially averaged samples, investigators can zoom in ultimately to the locally small but statistically significant short-term changes in species abundances within one wetland or forest stand. A zoom lens perspective is possible for eastern North America and Europe and is becoming possible in western North America and other regions.

Two examples using current data illustrate this zoom lens view. The first holds time relatively constant and focuses up spatially from local to continental (Figures 1–3), and the second zooms in from a 1-My timescale down to successional changes during the past 300 years (Figure 4). The first example covers the past 21,000 years since the last glacial maximum in the northern Midwest and focuses up from a local to a continental perspective. It shows how the local changes in a wetland during the past 12,000 years in central Minnesota are

part of regional climate changes that ultimately reflect the global climate changes during deglaciation and the current interglacial period.

At the local scale of the sampling basin, plant macrofossils, aquatic pollen, and diatoms at Kirchner Marsh in east-central Minnesota illustrate that 3000 years after the Laurentide ice sheet retreated from the sites *ca.* 19,000 years ago, a buried ice block melted to form the kettle basin and its associated lake (Kutzbach and Webb, 1991). Water levels were high until approximately 11,000 years ago when the seeds of damp ground and weedy annuals began appearing in the core (Watts and Winter, 1966). These appeared when the mixture of oak and herb pollen data show the first evidence of oak savanna conditions within the landscape and region near the site (Figure 1). When the herb pollen values increased sufficiently to indicate prairie vegetation near the site, large fluctuations in aquatic seeds indicated intermittent droughts that continued until a marsh developed at the site 2000 years ago. This history of local wetland development is closely linked to the vegetation and climate changes indicated at the landscape, regional, and continental levels (Figures 1–3).

Here, there is a shift from the time series view provided by local pollen and macrofossils to the continental view that the maps of pollen data provide. These show how 15,000 years ago spruce trees grew initially in a parkland that became populated with deciduous trees, first ash and then birch and oak, from 14,500 to 12,000 years ago as forests began to develop near the site for the first time (Figure 1). This early vegetation was unlike any growing today and illustrates the major compositional changes in vegetation that accompanied the major changes in climate (Williams and Jackson, 2007). The sudden decrease in spruce abundance near Kirchner Marsh 12,500 years ago reflects the general northward movement and decrease in regional and continental spruce populations as climate warmed and the ice sheet retreated. Pine populations were then invading from the east to replace the birch trees that briefly grew abundantly near the site and in the northern Midwest generally. Oak and elm populations then increased to replace the pines as the climate warmed. The regional addition of herb pollen after 11,000 years ago signals the development of savanna conditions as the climate dried and the ice sheet retreated further north. The savanna grew until prairie vegetation developed approximately 8000 years ago as the grasslands spread from the west across Minnesota and the northern Midwest. By then, the ice sheet had almost disappeared and spruce populations were beginning to grow abundantly in eastern and central Canada where the boreal forest has developed today. With the retreat westward of the prairie-forest ecotone after 6000 years ago, open oak forests began growing near the lake that with further growth in aquatic vegetation became a marsh after 2000 years ago. Oak populations then decreased regionally as part of a general retreat of oak in the north as conifer populations increased and spruce populations increased south from Canada into the northern Midwest and New England. The broad-scale regional and continental maps show how the local and landscape changes in vegetation fit within the broader context of changes.

The second example is a zoom lens perspective in time (Figure 4) and shows time series for taxa reflecting the long-

term temporal beat in climate at long time scales (1.5 My to 16,000 years) but then shifting to reflect fires, disease, and other disturbances at shorter timescales, especially when the pollen data are derived from within a forested hollow. Within the latter, the pollen reflects local changes in trees next to the site.

This arrangement and description of the data allow paleoecologists to zoom in or out in space–time to observe different aspects of vegetation dynamics and patterns of biodiversity from long-term changes on several spatial scales (from continental to inside the forest canopy) to competitive interactions after disturbance within communities. With such an ordering of data and images, the interconnected roles and impacts of climate change, disturbance, disease, succession, soil development, competition, and evolution can all be observed and potentially distinguished from one another in studies of past biodiversity. To this end, recent studies of sediment records are including data on charcoal, sediments, biomarkers, isotopes, biogeochemistry, and plankton that provide evidence for environmental changes from fires to climate that can be used to help interpret the changes in the vegetation (Whitlock *et al.*, 2003; Webb *et al.*, 2003).

Mapping and studying pollen and plant macrofossil data in space–time have been convincing of the potential for resolving many different views of the past. No single fixed picture is possible because there is no preferred viewing scale or perspective, nor is there any one way to describe the vegetation and biodiversity. Many conventional displays and perspectives are used, but some, such as traditional pollen diagrams, may not be optimal for interpreting key variations in the vegetation. A zoom lens perspective in space and time is required to help explore all the possibilities and to allow for diverse narratives and explanations. Succession and patch dynamics are evident with data scaled to meters and decades, whereas climatically induced migrations and abundance changes appear best over thousands of kilometers and years. To zoom out from a local to a global view, the paleoecological data need to be organized so that highly resolved images of species near a site give way to more generalized averages of data values whose patterns will stand out sharply when viewed across continents or the world. Appropriate study of assembled databases should allow ecologists to resolve and perceive a variety of phenomena, such as ecotones, disturbance horizons, species distributions, and migration patterns, that are important for biodiversity.

Glossary

Classification The process of assigning the pixels of an image to discrete categories.

Electromagnetic radiation The energy transmitted through space in the form of electric and magnetic waves that can be detected by various types of sensors.

Geographic information systems (GISs) Computer systems that store, enhance, analyze, and display layers of geographic data and connect these to alphanumeric databases.

Image processing The manipulation of digital image data, including operations such as image display, restoration, enhancement, and classification.

Pixel Abbreviated from “picture element,” the smallest part of a picture (image).

Sensor A device that gathers energy, converts it to a digital value, and presents it in a form suitable for obtaining information about the environment.

Introduction

It is now widely recognized that biodiversity is a multi-dimensional and multiscale phenomenon encompassing different organization levels (populations, species, functional groups, communities, ecosystems, and landscapes) and a wide range of spatial scales (from microhabitat heterogeneity to global-scale patterns). Identifying patterns of biodiversity and their causal factors is therefore an enormous task that requires (1) mapping and monitoring of biological patterns across different spatial and temporal scales and (2) analysis of such patterns with respect to diverse aspects of the physical and human environment. Remote sensing is one of the best tools available for coping with this challenge. Information obtained from remote sensing is intrinsically multidimensional (horizontally, vertically, temporally, and spectrally) and may cover spatial scales ranging from a few centimeters to entire continents (Figure 1). Data derived from remote sensing provide information on all levels of biological organization, including species, functional groups, ecosystems, and biomes. These capabilities make remote sensing an extremely valuable tool for studies of biodiversity.

The aim of this article is to draw attention to the potential and actual contribution of remote sensing to studies of biodiversity. The article consists of two main sections. The first section introduces fundamental concepts of remote sensing. The second section discusses applications of how remote sensing is being used for mapping, monitoring, and modeling patterns of biodiversity. The article is concluded by a brief summary that points to some current and expected future developments in this field.

Fundamentals of Remote Sensing

An Overview of the Remote-Sensing Process

Remote sensing can be broadly defined as “the technique of obtaining information about objects through the analysis of

data collected by special instruments that are not in physical contact with the objects of investigation” (Avery and Berlin, 1992). A refined definition of remote sensing that better fits the scope of this article is: “The practice of obtaining information about the Earth’s surface, using images acquired from airborne or spaceborne vehicles by measuring reflected, emitted, or returned electromagnetic radiation.”

This narrower definition restricts our discussion to applications in which the general target of the observation is the Earth’s surface, the measured energy is electromagnetic radiation, and the sensors are positioned on airborne or spaceborne platforms. Although some techniques of remote sensing do not fit this formalization (e.g., acoustical or sonar technologies), the above definition covers most of the methods that are currently applied for the documentation, monitoring, and mapping of biodiversity.

Figure 2 schematically illustrates the basic elements of the remote-sensing process. Any remote-sensing application consists of two distinct processes: data acquisition (detection and recording of electromagnetic radiation) and data analysis (extraction of information from the recorded data). The first process can be performed either photographically (i.e., by a photographic camera) or electronically (by electronic sensors). A photographic camera uses optical lenses and a light-sensitive film to detect electromagnetic radiation. The film acts as both the detector of the radiation and the recording medium. Electronic sensors convert electromagnetic radiation into electronic signals that can be stored as digital images. The end product of this stage of remote-sensing is therefore either a photograph or a digital image. Most current remote-sensing systems produce digital images.

The second step of the remote-sensing process is data analysis (Figure 2). Remotely sensed data, either photographs or digital images, must be analyzed in order to provide useful information about the observed features. Analytical techniques available for the analysis of remotely sensed data are diverse, ranging from traditional methods of visual interpretation to sophisticated computer-based image processing. The final product of both visual interpretation and computer-based

Figure 1 A global map of land cover derived from data acquired by MERIS.

Figure 2 Basic elements of the remote-sensing process.

image processing is usually a map showing the spatial distribution of the variables of interest. Maps generated from remotely sensed data can be used directly, or in combination with other data sources, for a variety of applications, including research, decision making, planning, and management.

Electromagnetic Radiation and Its Measurement

As already defined, remote sensing is concerned with the measurement of electromagnetic radiation reflected, emitted, or returned from objects and features on the Earth's surface. In passive remote sensing, the sensor measures radiation reflected

or emitted from the surface. The main source of radiation reaching the Earth is the Sun. Some of the solar radiation is reflected from the Earth's surface and can therefore be detected by cameras or electronic sensors. Other components of the solar radiation are absorbed at the Earth's surface and are reradiated as thermal energy. This form of electromagnetic radiation can also be detected and recorded by appropriate sensors. As different objects emit and reflect different types and amounts of radiation, images capturing such differences contain much information on the nature of the Earth's surface. In active remote sensing, the sensor sends its own electromagnetic energy to a target and measures the returned radiation.

The Electromagnetic Spectrum

A basic characteristic of electromagnetic radiation is its wavelength. Solar radiation consists of a wide and continuous range of wavelengths, stretching from $<10^{-6}$ to $>10^7$ μm ($1\text{ }\mu\text{m} = 10^{-6}\text{ m}$). This continuum is subdivided into several divisions called spectral bands, which share similar characteristics (Figure 3(a)). The main bands used in remote sensing are ultraviolet (UV), visible, infrared (IR), and microwave. The UV band lies between the X-rays and visible light with wavelength limits of 0.01 and 0.4 μm (Figure 3(a)). Wavelengths shorter than 0.3 μm are unable to pass through the atmosphere and therefore only the 0.3–0.4 μm wavelength interval, or near-UV, is available for remote sensing (Figure 3(b)).

The visible band stretches from 0.4 to 0.7 μm (Figure 3(a)). This spectral range constitutes an extremely small portion of the full electromagnetic spectrum and its boundaries are defined by the wavelength limits of human vision (Figure 3(b)). The visible spectrum is further subdivided into three equal segments: blue (0.4–0.5 μm), green (0.5–0.6 μm), and red (0.6–0.7 μm).

The IR band extends from 0.7 to 1000 μm (Figure 3(a)). In remote sensing, this wide band is divided into two major components: the reflected IR band (from 0.7 to 3.0 μm) and the emitted, or thermal, IR band (from 3.0 to 1000 μm). The first component is essentially solar radiation reflected from the Earth's surface. This component is further subdivided into near-IR (<1.3 μm) and mid-IR (>1.3 μm). Radiation in the near-IR behaves, with respect to optical systems, in a manner analogous to radiation in the visible spectrum. It can therefore be detected and recorded by films and cameras similar to those used for the visible spectrum. The thermal component

of the IR spectrum represents heat energy that is continuously emitted by all objects on the Earth's surface. It ranges from 3 to 1000 μm , but wavelengths beyond 14 μm are largely absorbed by the atmosphere and are therefore not available for remote sensing (Figure 3(b)).

The microwave band falls between the IR and the radio bands (Figure 3(a)). It ranges from approximately 1 mm to 1 m and contains the longest wavelengths used in remote sensing. An important feature of microwave radiation is its ability to pass through clouds, precipitation, and tree canopies.

Types of Remote Sensors

The sensors used in remote sensing can be divided into four main groups:

1. Photographic camera sensors.
2. Electro-optical sensors.
3. Passive microwave sensors.
4. Active sensors.

Photographic cameras can detect wavelengths ranging from approximately 0.3–0.9 μm (Figure 3(b)). This includes the near-UV band (0.3–0.4 μm), all the visible light (0.4–0.7 μm), and the relatively short wavelengths of the near-IR (0.7–0.9 μm). This spectral range, which is nearly twice as wide as the human vision, can be recorded directly into film and is therefore referred to as the photographic spectrum.

Electro-optical sensors measure radiation in narrow wavelength ranges that can be located at various points along the near-UV, visible, reflected IR, and thermal IR spectral bands

Figure 3 Characteristics of electromagnetic radiation. (a) Major divisions of the electromagnetic spectrum (not to scale). (b) Spectral ranges of common remote-sensing systems.

(Figure 3(b)). This spectral range (0.3–14 μm) is termed the optical spectrum because wavelengths in this range can be reflected and refracted using optical devices such as lenses and mirrors. An important characteristic of electro-optical sensors operating at the thermal IR band is their ability to collect data day and night without being sensitive to dust and haze.

Passive microwave sensors are designed to measure microwave radiation that is naturally emitted from the Earth's surface. These sensors operate at a spectral range of 0.15–30 cm (Figure 3(b)).

Active sensors emit radiation and measure the amount of radiation returned to the sensor. Radar systems are active sensors that transmit artificially produced energy to the Earth's surface and record the reflected component of this radiation. Radar can penetrate through clouds in contrast to optical systems that are severely challenged by cloud cover. Light detection and ranging laser (LIDAR) is another type of active sensor that emits radiation in optical wavelengths and can measure the distance to a target on the surface. LIDAR systems cannot penetrate through clouds.

Three forms of remote sensing can therefore be distinguished: the detection of solar radiation reflected from the Earth's surface, the detection of radiation emitted from the Earth's surface, and the detection of radiation transmitted from the sensor itself.

Sources of Remotely Sensed Data

Very High-Resolution Images

Aerial photography is the oldest form of remote sensing. Despite the increasing availability of more sophisticated imaging systems, aerial photographs remain one of the most reliable and widely used sources of remotely sensed data. High spatial resolution enables one to detect and analyze patterns at very fine spatial scales. The availability of historical aerial photographs makes it possible to measure and analyze long-term ecological processes.

Both black-and-white and color photographs are used in remote sensing. Historically, black-and-white photographs were taken with either panchromatic film or IR-sensitive film. Panchromatic film is characterized by an aggregate spectral sensitivity that includes the near-UV, blue, green, and red wavelengths (0.25–0.7 μm). It provides a tonal rendition that closely approximates the brightness of the scene being photographed and can be used to distinguish between objects of truly different color. IR-sensitive film has spectral sensitivity that extends from 0.25 to approximately 0.9 μm . This range encompasses the near-IR band in addition to the near-UV and visible wavelengths. Thus, IR-sensitive film operates beyond the confines of the visible spectrum and can be used to detect information that is unavailable for human vision. IR-sensitive films are especially valuable for vegetation classification because differences between vegetation classes are often more distinct in the near-IR than in the visible range (Figure 4).

Although the information contained in black-and-white photographs is expressed by differences in gray levels, color films offer the additional qualities of hue (dominant wavelength), chroma (color strength), and value (color intensity). This added information greatly improves interpretation

Figure 4 Generalized spectral reflectance curves for deciduous (broad-leaved) and coniferous (needle-bearing) trees. Note that both reflectance intensity and differentiation ability are highest in the near-IR region.

ability. Two kinds of color films historically used in aerial photography are normal color films and color IR films. Normal color films are sensitive primarily to wavelengths of the visible spectrum and provide a color rendition that approximates the original scene as it would be viewed by the human eye. This facilitates photo interpretation because objects appear in their natural colors. Color IR films are sensitive to green, red, and near-IR radiation (0.5–0.9 μm). Because maximum reflectance from vegetation occurs in the near-IR spectral region, such films are highly valuable for studies of vegetated landscapes. At present, aerial photos generally produce digital images with the digital values representing the electromagnetic radiation in different wavelengths (*see* Sources of Remotely Sensed Data: Satellite Imagery). Many types of sensors can be mounted on airplanes, including hyperspectral sensors to measure reflectance in many wavelengths and active LIDAR sensors.

A number of commercial satellites have been launched to obtain data at very high spatial resolutions (5 m or less) with panchromatic and multispectral bands, such as IKONOS (named after the Greek term for “image”) and Quickbird. These levels of spatial resolution approximate the resolution obtained by standard aerial photography.

Satellite Imagery

Data acquired by spaceborne imaging systems are usually recorded in digital form and are therefore available as digital images. A digital image is composed of a two-dimensional array of picture elements (pixels), with each pixel corresponding to a particular area on the ground. The radiance measured over the ground area represented by each pixel is translated into a digital number (DN). This number (also referred to as brightness) is a positive integer expressing the

average intensity of radiance measured from the particular ground area. Two important characteristics of digital images are spatial resolution and radiometric resolution. Spatial resolution refers to the size of the ground area represented by each pixel in the image. For example, a spatial resolution of $10\text{ m} \times 10\text{ m}$ means that each pixel in the image corresponds to a ground unit of $10\text{ m} \times 10\text{ m}$. The term radiometric resolution refers to the number of DN values, or brightness levels, used for recording differences in radiation intensity. Thus, a higher radiometric resolution permits the detection of finer differences in radiation intensity. Both spatial and radiometric resolution has important consequences for the amount of information available in remotely sensed data.

Satellite images suitable for mapping, monitoring, and modeling patterns of biodiversity have usually been derived from multispectral sensors measuring reflected or emitted radiation in the optical spectrum ($0.3\text{--}14\text{ }\mu\text{m}$). Imaging systems operating at this spectral range have been used in a variety of national and international Earth observation programs. Three of these programs, namely, Landsat, Systeme Pour l'Observation de la Terre (SPOT), and National Oceanic and Atmospheric Administration (NOAA) Advanced Very High-Resolution Radiometer (AVHRR), provide multidecadal observations and are of particular importance for studies of biodiversity. The main characteristics of these programs are outlined below. Many other sensors are useful for biodiversity, including multispectral optical sensors MODIS (Moderate Resolution Imaging Spectroradiometer) and MERIS (Medium Resolution Imaging Spectrometer), radar, hyperspectral, and LIDAR (Light Detection and Ranging). The three programs discussed below (Landsat, SPOT, and coarse resolution sensors) provide the longest time series, which is often important in biodiversity studies to assess change in habitat. Emerging technologies that are promising for biodiversity studies are also discussed.

Landsat Program

The Landsat program is the longest running project for acquisition of repetitive multispectral data of the Earth's surface. The first Landsat satellite was launched in 1972 and the most recent one (Landsat 7) in 1999. Landsats 1–3 covered the Earth every 18 days. Landsats 4, 5, and 7 have a coverage cycle of 16 days (Landsat 6 has failed to achieve orbit). At present (2011), the only active satellites in this program are Landsats 5 and 7. However, data recorded by earlier Landsat missions are still being used in many remote-sensing applications.

Table 1 compares the characteristics of data acquired by the two main sensors used in the Landsat program, the Multispectral Scanner (MSS) and the Thematic Mapper (TM) and Enhanced Thematic Mapper (ETM). The MSS collects reflected solar radiation in four contiguous spectral bands, two in the visible spectrum at $0.5\text{--}0.6\text{ }\mu\text{m}$ (green) and $0.6\text{--}0.7\text{ }\mu\text{m}$ (red), and two in the near-IR at $0.7\text{--}0.8$ and $0.8\text{--}1.1\text{ }\mu\text{m}$. This imaging system was used by Landsats 1–5 (note that the same spectral bands had different numbering systems in Landsats 1–3 and Landsats 4 and 5). Data collected by the MSS are framed into individual scenes that cover a nominal ground area of $185\text{ km} \times 185\text{ km}$ at a spatial resolution of 79 m in Landsats 1–3 and 82 m in Landsats 4 and 5 (**Table 1**).

Table 1 Characteristics of Landsat MSS and TM Data

<i>Band</i>	<i>Wavelength range (μm)</i>	<i>Nominal spectral location</i>	<i>Spatial resolution (m)</i>
<i>MSS^a</i>			
4 (1)	0.5–0.6	Green	79 (82)
5 (2)	0.6–0.7	Red	79 (82)
6 (3)	0.7–0.8	Near-IR	79 (82)
7 (4)	0.8–1.1	Near-IR	79 (82)
<i>TM and ETM</i>			
1	0.45–0.52	Blue-green	30
2	0.52–0.60	Green	30
3	0.63–0.69	Red	30
4	0.76–0.90	Near-IR	30
5	1.55–1.75	Mid-IR	30
6 ^b	10.4–12.5	Thermal IR	60,120
7	2.08–2.35	Mid-IR	30
8 ^c	0.52–0.90	Panchromatic	15

^aMSS bands of Landsats 1, 2, and 3 are numbered 4–7. The same bands are numbered 1–4 in Landsats 4 and 5. Spatial resolution is 82 m in Landsats 1–3 and 30 m in Landsats 4, 5, and 7 (thermal band 60 m).

^bThe thermal band is 120-m resolution on TM and 60-m resolution on ETM.

^cPanchromatic band 8 was added to ETM on Landsat 7.

The TM was designed to improve the imaging capabilities of Landsat satellites. A major difference between the TM and the MSS is the acquisition of data in seven bands instead of four, with new bands in the visible (blue-green), mid-IR, and thermal portions of the spectrum (**Table 1**). Also, based on experience with MSS data and extensive research, the wavelength range and location of the TM scanner have been modified to facilitate the spectral differentiability of major Earth surface features. The radiometric resolution of the TM is higher than that of the MSS (256 vs 64 DNs) and its spatial resolution is also higher (30 m for all bands except the thermal band, as compared with approximately 80 m in the case of the MSS). These overall capabilities significantly improved the spectral coverage, radiometric resolution, and spatial resolution of Landsat images. The ETM has a panchromatic band at a 15-m resolution.

Since 2008, all images in the Landsat archive are available for download at no charge.

SPOT Program

SPOT is an international Earth observation program initiated by the French government in the late 1970s. The first SPOT satellite was launched in 1986, and the most recent one (SPOT 5) in 2002. All satellites have an Earth-coverage cycle of 26 days. The sensors of SPOT 1, 2, and 3 consist of two identical high-resolution visible (HRV) imaging systems, each designed to operate in either of two modes: a black-and-white panchromatic mode over the range $0.51\text{--}0.73\text{ }\mu\text{m}$ (green–red) and a multispectral mode over the ranges $0.50\text{--}0.59\text{ }\mu\text{m}$ (green), $0.61\text{--}0.68\text{ }\mu\text{m}$ (red), and $0.79\text{--}0.89\text{ }\mu\text{m}$ (near-IR). Spatial resolution of the panchromatic mode is 10 m , whereas that of the multispectral mode is 20 m . SPOT 5 has a higher resolution of $2.5\text{--}5\text{ m}$ in the panchromatic mode, 10 m in multispectral mode, and 20 m for short-wave IR band. The data are encoded over a range of 256 DNs, and individual

images are formatted to cover a $60 \text{ km} \times 60 \text{ km}$ area. An important advantage of the HRV imaging system is the ability to adjust its viewing angle by ground commands, and thus to observe the same location several times within the normal 26-day coverage cycle. This "revisit" capability facilitates the documentation and monitoring of short-term dynamic processes (e.g., vegetation responses to episodic rainfall or drought events). It also increases the chance of obtaining cloud-free images in areas where cloud cover is a problem.

Coarse-Resolution Sensors

The NOAA of the USA operates national weather programs that rely to a large extent on data collected by meteorological satellites. Imaging systems of such satellites are usually designed to have a relatively low spatial resolution, but very high temporal resolution. Satellites of the NOAA series, one of the longest weather satellite programs, observe the complete Earth twice a day at a ground resolution of $1.1 \text{ km} \times 1.1 \text{ km}$ at nadir. These satellites carry a multispectral scanner known as the AVHRR. The AVHRR was designed primarily for meteorological applications, but it has been applied successfully for many land-oriented applications. Details of the specific spectral coverage vary with the specific mission, but in general, AVHRR sensors collect data in four or five bands falling in the visible, near-IR, and thermal IR spectral regions. Images acquired by AVHRR are available at a full 1.1-km resolution (local area coverage) and at a subsampled resolution of 4 km (global area coverage). In 2000, the US National Aeronautics and Space Administration (NASA) launched the MODIS sensor as part of Earth Observations System platform. MODIS acquires daily images at 250 m in the red and IR bands, 500 m at other spectral bands, and 1 km in thermal bands. MERIS is a European coarse-resolution sensor launched in 2002, but data are less easily available than from AVHRR or MODIS.

Emerging Technologies

Several remote-sensing technologies are not as well developed as the long-term time series (Landsat, SPOT, and coarse resolution sensors) but research is demonstrating the utility of these emerging technologies for biodiversity studies. Hyperspectral scanners are imaging systems that acquire multispectral images in many, very narrow, contiguous spectral bands throughout the visible, near-IR, and mid-IR portions of the spectrum. This spectral capability permits discrimination among objects that have fine diagnostic reflection characteristics that are "lost" within the bands of conventional electro-optical scanners. For example, Airborne Visible/Infrared Imaging Spectrometer (AVIRIS), one of the main hyperspectral scanners, collects data in 224 contiguous bands between 0.4 and $2.45 \mu\text{m}$.

Other emerging technologies are active LIDAR and radar sensors. These sensors provide information on three-dimensional vegetation structure that can indicate characteristics of habitats. Airborne sensors have tested these technologies. To date (2011) hyperspectral and LIDAR sensors are not flown on spaceborne satellites. Some satellites obtain radar data, such as the Advanced Land Observation Satellite (ALOS), which was launched in 2006 and lost power in 2011.

Imaging radars have been used for remote sensing since the late 1970s. However, most of these applications were of

experimental nature. For example, the Shuttle Imaging Radar carried by the space shuttle Columbia in its second flight was used to collect data from different continents in an attempt to construct a library of images representing a wide variety of environments differing with respect to climate, geology, vegetation, and other qualities. More recent studies have evaluated the potential of radar data for vegetation mapping, detection of deforestation, determination of vegetation biomass, and estimation of various forest parameters. Such applications have led to a better understanding of the capabilities of radar imagery and demonstrated that this form of remote sensing may complement many characteristics of images based on the optical spectrum.

Analysis of Remotely Sensed Data

Data obtained from remote sensing must be interpreted in order to become usable information. The outcome of the interpretation process is usually a map showing the spatial distribution of the objects or variables of interest. Such maps can be analyzed with respect to other sources of information using geographical information systems (GIS) (*see* Integration of Digital Images within a GIS Environment).

Interpretation of Remotely Sensed Data

In the case of aerial photographs, the interpretation process is often based on visual examination: The interpreter systematically examines the image (and possibly supporting materials such as maps or field reports) and tries to identify the nature of the objects and phenomena seen in the image. This form of image interpretation relies on the ability of the human mind to qualitatively evaluate spatial patterns in an image. In most cases, it involves the identification and delineation of discrete areal units throughout the image. For example, in studies of vegetation variation, the interpreter outlines the boundaries between areas covered by different vegetation types.

Digital images are usually interpreted using computer-based image processing. Recall that the brightness of each pixel in a digital image is expressed by a numerical integer (its DN value); the general objective of image processing is to "translate" the original image into a more informative image by mathematically manipulating the recorded DN values. Practically this is done by subjecting the original image, pixel by pixel, to appropriate mathematical operations and storing the results of the computation as a new image. The mathematical algorithms used in image processing are literally infinite, but most kinds of algorithms can be categorized into one of three main operations: image restoration, image enhancement, and thematic classification.

Image restoration involves various operations of spectral and geometric corrections. Digital images are noisy and suffer from different kinds of spectral and geometric distortions that reduce their quality and limit their use. For example, the spectral characteristics of objects detected in a digital image are distorted by differences in sun angle, topographic variation, atmospheric scattering, and sensor characteristics. All of these factors may influence the intensity of electromagnetic radiation measured by the sensor. Other factors may introduce

positional errors to digital images. Radiometric corrections are mathematical operations that compensate for various sources of spectral distortion in the data. Geometric corrections attempt to correct for positional errors and to transform the original image into a new image that has the geometric characteristics of a map.

Image-enhancement operations attempt to improve the detectability of objects or patterns in the image. For example, contrast-stretching algorithms increase the contrast between features of interest and thus improve interpretation ability. Edge enhancement algorithms are designed to automatically detect boundaries between different kinds of features. Other algorithms operate on multispectral data. For example, vegetation indices (VIs) represent a group of spectral operations that attempt to enhance vegetation mapping and monitoring. The most widely used VI is the normalized difference vegetation index (NDVI) defined by the general equation

$$\text{NDVI} = \frac{\text{near-IR band} - \text{red band}}{\text{near-IR band} + \text{red band}}$$

This index can be computed using data acquired by a variety of imaging systems (e.g., Landsat, SPOT, NOAA AVHRR, and MODIS) and has proved to be a sensitive indicator of the presence and condition of green vegetation.

Thematic classification is a process of assigning all pixels of an image into land-cover classes (themes) based on their DN values. In applications such as land cover or vegetation mapping, thematic classification is the main object of the analysis. The outcome of the classification process is a new image where each pixel represents a particular land-cover type. Such an image can be interpreted as a map depicting the spatial distribution of the selected land-cover types within the scene (Figure 1).

Two standard approaches for image classification are unsupervised classification and supervised classification. In unsupervised classification the pixels of the image are numerically classified into a number of spectral classes based on the likeness of their DN values. The land-cover identity of each spectral class is then determined using reference information such as field data, aerial photographs, or published maps. In supervised classification, the analyst first selects areas of known cover type in the image. These "training sites" are analyzed statistically to identify the spectral characteristics of each cover type. With appropriate algorithms, the DN values of each unknown pixel in the image are compared with those of the training sites, and the pixel is assigned to the land-cover type to which it is most similar. It is important to emphasize that classification of digital images is never perfect. The success of image classification depends on many factors and may vary considerably from one case to another. Therefore, any classification of remotely sensed data must be followed by some form of accuracy assessment.

Traditional classification approaches are based on the spectral values of a pixel. The pixel-based approach classifies each pixel independent of the neighboring pixels. In contrast, object-oriented classification considers the spectral characteristics of a pixel along with spatial information from texture and context information in the image. The image is segmented into objects that form the classification units. Objects rather than single pixels are considered in the classification process.

Integration of Digital Images within a GIS Environment

GISs are computer-based systems capable of storing, manipulating, and visualizing geographically referenced data. Basically, any kind of information that can be presented by standard maps can be converted into digital form and handled by GIS. An important benefit of GIS is the ability to spatially integrate multiple types of data stemming from different sources of information. A typical GIS operation is overlay analysis. Many other kinds of spatial operations can be performed with GIS. For example, aggregation is an operation by which detailed map categories are aggregated into less detailed categories (e.g., aggregation of detailed vegetation units into a few broad vegetation types). Buffering is an operation by which a zone of user-defined width is created around map objects. Data merging is an operation by which different grid maps of the same area are coregistered into a uniform, multidimensional database. This operation is commonly applied to combine digital images representing different wavelengths, different times of observation, or different sensors. For example, monitoring seasonal variation in NDVI requires the coregistration of images taken at different times. Low-resolution images (e.g., AVHRR) can be merged with images of higher resolution (e.g., Landsat TM) for calibration or interpretation purposes. Using the merging capability of GIS, one is able to coregister digital images with "ancillary" data (e.g., elevation and slope) that correspond to each pixel in the image. Once such data are spatially registered, information available in the GIS can be used to improve image classification. Thus, the interaction between remote sensing and GIS is two way in nature; remote sensing is used to generate digital maps that can be fed into GIS, whereas GIS data can be used to interpret and classify remotely sensed data.

GIS can also be used for modeling purposes. For example, by overlaying vegetation maps derived from remote sensing with corresponding maps of climatic and topographic variables, one is able to develop regression models that predict vegetation characteristics from information on climate and topography.

Applications of Remote Sensing for Studying Biodiversity

The previous section (Analysis of Remotely Sensed Data) has focused on general concepts and elements of remote sensing. Its main purpose was to provide the scientific and technical background required to understand how remote-sensing technology can be used for collecting, analyzing, and visualizing images of Earth's surface. This section presents three major applications to illustrate the wide spectrum of biodiversity issues that can be studied with remote sensing.

Three main kinds of applications are: (1) mapping of land cover and vegetation patterns, (2) measurement of temporal changes in land cover and vegetation characteristics, and (3) modeling of species distribution patterns. The applications can occur at global, regional, or local scales with increasing amounts of spatial detail. This trade-off between spatial scale and spatial resolution is a common characteristic of remote-sensing applications. Temporal intervals between cloud-free successive satellite images of the same system range from daily to annually and spatial resolutions range from meters to

kilometers. Generally an application can cover large areas at coarse spatial resolution or small areas at fine spatial resolution. These differences point to the diversity of spatial and temporal scales that can be investigated using remotely sensed data.

Remote sensing provides proxies for patterns and changes in biodiversity. Species are not directly observable with remote sensing. Remote sensing of habitat distribution and quality provide indirect measures of biodiversity patterns (Hansen *et al.*, 2010).

Mapping Vegetation and Land-Cover Patterns

Mapping vegetation and land-cover patterns has been the most common application of remote sensing. It may contribute to studies of biodiversity both directly (by documenting the distribution of different components of biodiversity) and indirectly (by providing knowledge on landscape and habitat characteristics that influence patterns of biodiversity). Land-cover maps categorize each grid cell according to a predefined

Figure 5 Global-scale estimated percent tree cover (reproduced from Hansen M, Stehman S, and Potapov P (2010) Quantification of global gross forest cover loss. *Proceedings of the National Academy of Sciences of the United States of America* 107: 8650–8655).

Figure 6 Four-meter multispectral IKONOS data for La Selva Biological Station, Costa Rica, for mapping tree crowns (reproduced from Clark D, Read J, Clark M, Cruz A, Dotti M, and Clark D (2004) Application of 1-m and 4-m resolution satellite data to ecological studies of tropical rain forests. *Ecological Applications* 14: 61–74).

classification system, either as a discrete cover type or as a mixture of vegetation characteristics such as woody, grass, or bare ground.

Global land-cover maps are generally derived from data with relatively coarse spatial resolution and high temporal resolution. Discrimination among cover types is based on spectral signatures of different cover types and the temporal differences in phenology. Global land-cover maps are useful for indicating biome-level diversity and broad-scale patterns of where different species might occur. At a finer spatial resolution, data from the Landsat sensor have been the workhorse for mapping vegetation patterns. Individual scenes cover $185 \text{ km} \times 185 \text{ km}$. Land-cover maps over larger areas can be constructed by mosaics of multiple images although technical difficulties arise if the images are acquired on different dates. At an even finer spatial resolution, very high-resolution satellite or aerial data can be used to map land-cover patterns in

more detail but over relatively small areas. The appropriate data and scale for land-cover maps depend on the application for broad-scale biodiversity studies (global and regional scale maps) or fine-scale, detailed maps for biodiversity patterns in a specific place. **Figures 5 and 6** illustrate the range of scales from global distribution of forest cover using MODIS data (**Figure 5**) to mapping tree crowns from very high-resolution IKONOS data (**Figure 6**).

Land-cover maps produced from remote sensing can be combined in a GIS with other layers such as precipitation, temperature, soil type, and human settlements to infer species distributions.

Measuring Vegetation Changes

Identifying patterns, scales, and trends of vegetation changes is important for understanding the dynamics and structure

Figure 7 Annual change from 1998 to 2003 in forest degradation from selective logging and burning in Sinop region, Mato Grosso state, Brazil, depicted from Landsat data. Graphic courtesy of Carlos Souza, Jr. (DeFries, 2008).

of both plant and animal communities. As with mapping applications, measurements of vegetation changes based on remotely sensed data may provide direct evidence for changes in biodiversity (e.g., changes in the relative frequency of different vegetation types) as well as information on environmental changes that may influence biodiversity patterns (e.g., deforestation and forest fragmentation). Mapping deforestation is a common application for remote sensing. Other more subtle changes in vegetation are also observable, such as logging and burn scars (Figure 7).

Measuring vegetation changes requires a time series of remote-sensing data that is calibrated to eliminate artifacts from changes in the sensor or atmospheric conditions. The long time series of Landsat data are commonly used to map change. At coarser resolutions, AVHRR provides a multidecadal time series and can be used to identify interannual variability and trends in vegetation from climate variability.

Modeling Species Distribution and Species Richness

Although most plant and animal species cannot be detected directly by remote sensing, the integration of data obtained from remote sensing with field-based observations of plants and animals enables one to develop statistical models that predict distribution patterns of individual species from information on the environment. A similar approach can be applied to model and predict patterns of species diversity.

Data from hyperspectral sensors are potentially useful for mapping species distributions based on the notion that species vary in upper-canopy pigments, water, and nitrogen content. In a study in Hawaiian lowland rainforests, species richness was significantly correlated with spatial variation in reflectances at wavelengths for measuring pigments (530 and 720 nm), canopy water (1201 nm), and leaf water/nitrogen (1523 nm) acquired by the airborne hyperspectral AVIRIS sensor. The results suggest that increasing spectral diversity is linked to increasing biochemical diversity which in turn is linked to plant species richness (Carlson *et al.*, 2007), demonstrating the utility of remote sensing for mapping diversity at high spatial resolution (Table 2).

LIDAR and radar data provide information about the three-dimensional characteristics of habitats, making it possible to model species distributions. Canopy structure is determined

Table 2 Pearson correlation coefficients (r) between woody species richness (RICH) and the AVIRIS reflectance derivatives at 530 and 720 nm (pigments), 1201 nm (canopy water), and 1523 nm (leaf water/nitrogen)

Variable	RICH	R_{d530}	R_{d720}	R_{d1201}	R_{d1523}
RICH	—				
R_{d530}	0.84	—			
R_{d720}	0.87	0.87	—		
R_{d1201}	0.77	0.74	0.70	—	
R_{d1523}	0.91	0.81	0.90	0.79	—

Relationships are significant at the $p < .01$ level.

from the backscatter of these active sensors, making it possible to map structure related to habitats for different animal species (Figure 8).

Other Applications

The applications presented above exemplify various aspects of biodiversity that can be investigated using remote sensing. Three additional aspects, not covered by these case studies, are mentioned here to provide a more complete picture of the subject. These are fire, grazing, and canopy gap dynamics.

Fire is a major source of disturbance in many kinds of ecosystems. Studies of fire distribution in space and time may therefore contribute to our understanding of the dynamics and structure of ecological communities. Active fires are detected using thermal wavelengths from the MODIS sensor and made publicly available (Figure 9). Burn scars are also mapped from optical sensors such as Landsat and MODIS.

Another aspect of biodiversity that has been studied extensively with remote sensing is grazing. Data obtained from remote sensing have been used to investigate vegetation responses to both natural and domestic grazing. Some studies have focused on spatial patterns (e.g., differences between fenced and nonfenced areas), whereas other studies were designed to quantify temporal vegetation changes caused by grazing (e.g., biomass removal, replacement of herbaceous vegetation by woody species, or shrub encroachment).

Canopy gaps caused by the death of one or more trees are a major disturbance mode in many temperate and tropical ecosystems. Such disturbances may have considerable effects on the diversity of plant and animal communities. Traditionally, studies of canopy gap dynamics have focused on simple “static” parameters such as gap size distribution and total gap area. An alternative (and more direct) approach for studying gap dynamics is to analyze time sequences of remotely sensed data.

Figure 8 Canopy structure of an approximately 1 km² area of La Selva Biological Research Station, Costa Rica, derived from airborne LIDAR sensor in 1998. Color is intensity of the LIDAR return at each height (green is lowest, red is highest). Graphic courtesy JE Weishampele (DeFries, 2008).

Summary

Remote sensing in general, and Earth observation satellites in particular, have brought a new dimension to understanding of the Earth's surface. Since the launch of the first Landsat satellite in 1972, millions of images of the Earth have been acquired from spaceborne imaging systems. Earth observation satellites have provided images over spatial scales ranging from local regions to global cover, at spatial resolution of a few meters to tenths of a kilometer, and at spectral wavelengths ranging from near-UV to microwave radiation. Some of these data have been acquired systematically and repetitively over many years, with temporal resolution ranging from hours to a few weeks. In addition, most of the Earth observation satellites were designed to provide multispectral images of the Earth's surface. This enormous amount of information has been utilized extensively for studies of biodiversity. As demonstrated in this article, data obtained from remote sensing have been used for mapping various components of biodiversity, measuring different ecosystem characteristics (e.g., forest structure), analyzing factors affecting the distribution of plant and animal species, monitoring natural and human-induced vegetation changes (e.g., succession and deforestation), and evaluating the impact of various disturbances (e.g., fire) and ecological interactions (e.g., grazing).

Recent advances in remote-sensing technologies and computing power have added to the toolkit from aerial photography and multispectral optical data. Hyperspectral and very high-resolution optical sensors as well as active LIDAR and radar sensors are increasing the contributions of remote sensing to the study of biodiversity. There are many reasons to

believe that in the near future much more information on biodiversity will be obtained from remote sensing. In parallel to these advances in space technology, new analytical methodologies are being developed for the analysis and interpretation of data from very high-resolution, hyperspectral, and active sensors. One can therefore expect a considerable growth in the contribution of remote sensing to studies of biodiversity during the next decade.

Glossary

Abiotic Nonliving components of ecosystem – the chemical and physical environment.

Biotic Living components of ecological community – organisms, species.

Covariate A variable that might predict the response of interest; also termed *predictor* or *explanatory variable*.

Extent A component of spatial scale: the size of the study domain.

Extrapolation Estimating the value of a response variable at unmeasured locations by extending a model to new places or times.

Geospatial data Digital representations of data about Earth, including geographic locations, stored in a geographic information system (GIS).

Grain A component of spatial scale: sample resolution, the size of a single observation.

Proximal Direct or causal – for example, a factor directly related to species distribution and abundance (in contrast with distal factors that may be surrogates or proxies for causal factors).

Introduction

Species distribution modeling (SDM) is a methodology – a set of procedures, definitions, and techniques – built on a foundation of core ecological (Whittaker *et al.*, 1973) and biogeographical (Holdridge, 1947) concepts about the relationship between species distributions (or other biotic response variables describing aspects of biodiversity) and the physical (abiotic) environment. SDMs are quantitative, empirical models of species–environment relationships typically developed using species location data (abundance, occurrence) and those environmental variables thought to influence species distributions. Sometimes biotic information (other species, vegetation types, etc.) is included as a predictor variable. Provided appropriate data are available, SDMs can be applied to any taxa, including marine, terrestrial, and freshwater species, and at any grain and extent. Although the models can provide insights into factors influencing patterns of biodiversity even without predicting to maps, often the models are extended to making spatial predictions using maps of the environmental predictors. The practice of SDM has flourished over the past four decades in part because geospatial environmental data have become so widely available. The spatial predictions as well as the models themselves can inform both basic and applied biodiversity research.

Some of the earliest uses of SDMs focused on the insight and explanation that the models or their mapped predictions can provide, and this role continues to be important to this day. For instance, Leathwick and Austin (2001) explored competitive interactions between tree species in New Zealand's forests in a dataset in which geographic disjunctions provided the equivalent of a natural removal experiment. Regression models relating plot-based estimates of tree density to environmental and biotic covariates indicated substantial competitive displacement (e.g., Figure 1). This was one of the first pieces of statistical evidence for competition effects under field conditions. A second example of this theory-oriented use of SDMs is the recent focus on examining evidence for, and

methods for detecting, niche shifts or niche conservatism under processes of invasion or speciation (e.g., Peterson, 2011).

Spatial (mapped) predictions from SDMs are also used as inputs to other analyses, particularly in conservation planning and reserve design. For example, Linke *et al.* (2008) modeled the distributions of 400 freshwater benthic invertebrate taxa and predicted to rivers in southern Australia. These predictions provided the information necessary for estimating the irreplaceability or conservation value of river catchments. SDMs are also used for environmental impact assessment and land-use planning to determine suitable locations for habitat restoration and species reintroductions and to predict the risk of species establishment in new areas, including invasive species, pathogens, and disease vectors. One of the fastest-growing uses of SDM for risk analysis is to predict the potential impact of projected patterns of anthropogenic climate change on

Figure 1 Density of the tree *Weinmannia racemosa* in relation to mean annual temperature, for 0, 25, and 100 stems per hectare of a competitor, *Nothofagus* (four species, combined). The values of all other environmental covariates were set to fixed levels. Note this is an example of a partial dependence plot (also called a *fitted function* or a *response curve*).

species distributions (Pearson and Dawson, 2003). This requires extrapolation from empirical models into novel environments, as does predicting species invasions, and this important issue will be discussed later (see Predicting to New Times and Places).

SDMs are applicable to varying geographic scales and levels of biological organization. They have been used to study the patterns and causes of species distributions and community properties such as species richness at large spatial scales – for example, for macroecological questions. Evolutionary biologists use SDMs to explore the geographic structure of variation within and between taxa in phylogeographic studies, and ecologists test hypotheses about geographic variation in species traits (Kozak *et al.*, 2008; Dobrowski *et al.*, 2011).

Recent works including Guisan and Zimmerman (2000), Pearson (2010), Elith and Leathwick (2009a), and Franklin (2010) have described SDM methodology (species and environmental data requirements, modeling methods, model evaluation and uncertainty) in considerable detail with numerous pointers to the burgeoning literature on all aspects of SDM. This article will focus on the role of SDMs in quantifying species–environment relationships (response curves), the ecological and geographical theory underpinning SDM model formulation, issues of sampling and data fundamental to constructing models that are well suited for strong inference and prediction, and what to do when you do not have that perfect dataset (minimum requirements, robust modeling approaches). We will briefly discuss applying the SDM framework to biodiversity variables other than species, such as diversity measures or community composition, and address the critical issues involved when extrapolating predictions from SDMs to novel environments. Despite the importance of relevant and probing evaluations of model fit and predictive performance (accuracy), we only mention these topics briefly because their details will vary with the application, and they are covered in detail in the cited works.

Some Fundamentals

Niches

An important piece of ecological theory underpinning SDMs is niche theory. Here we will rely heavily on a recent paper by Colwell and Rangel (2009) that presents the theory in ways particularly relevant to SDMs, but many other authors including Peterson, Soberón, Chase and Leibold, Pulliam, Kearney, and Ackerly have made important contributions to the published discussion as summarized and referenced in Franklin (2010). It is G.E. Hutchinson's view of the niche that provides most insight and utility for SDMs. Hutchinson contended that the niche is an attribute of a species or population, with axes defined by those conditions (environmental attributes) and resources necessary for the persistence of the species. Thus the niche exists in niche space, defined by axes corresponding to environmental attributes (Hutchinson's "hypervolume") and without reference to the geographical space (biotope) in which species live. The biotope is the physical expression of niche axes. Hence there is an interesting and conceptually important duality or interplay between

niche space and the biotope (Colwell and Rangel, 2009; Elith and Leathwick, 2009a). Niche and biotope space are only partially reciprocal – that is, the correspondence of the two is not directly 1 : 1. Any one point in niche space might have many (or no) realizations in the biotope, whereas any one point in the biotope will link to only one point in niche space (Figure 2). This duality is applicable to any niche. The fundamental niche is that set of conditions that allow persistence (i.e., where population growth rate is not negative). A *potential distribution* is that subset of a species' fundamental niche that actually exists in the biotope at the current time. This need not be fully occupied and usually is not. Most species modelers view the realized niche as the physical expression of the fundamental niche, typically a subset of it due to biotic interactions, dispersal limitations, disturbances, and the difference between potential distributions and fundamental niches.

This all seems clear, but questions arise once we start to try to work out exactly what we are modeling when we have a set of data in hand and a model to use. We will cover some of these in following sections; also see Franklin (2010, Section 3.2.1). Suffice to say these questions have caused some modelers to decide to call their models *species distribution models*, emphasizing the origin of the data, focusing on predicting distributions, and avoiding a commitment to niches, whereas others prefer the term *ecological niche models* (ENMs) because niches are what they are most interested in. Certainly, all the applications that require predictions to new geographic regions (e.g., predicting potential distributions of invasive species) or new times (e.g., paleodistributions or under future climates) rely strongly on the conceptual links to niches.

The niche space–biotope duality has an important attribute: models fitted to niche axes are ignorant of physical distances between sites (Figure 2). The model uses identified relationships in niche space to predict to sites in the biotope. Any geographic patterning that occurs in the predictions (e.g., higher probabilities of occurrence being clustered together) results from the geographic patterning of the niche axes. This patterning is known as *spatial autocorrelation* (SAC; Legendre, 1993), meaning the dependencies among values of a given variable at different geographical separations. It is a common feature of environmental conditions on Earth and is the cause of many of the patterns we observe in nature. But geographic clumping of species is not always caused by SAC of environment: other factors including disturbance history, biotic interactions (positive and negative), life history traits (e.g., dispersal ability), and social behavior of individuals can play a role – these are all features of the biotope (though some could also be defined in niche space).

The topic of SAC and its role in and effect on species distributions is too complex to cover well here. There is an increasing body of relevant literature on topics, including how to measure SAC in model residuals, the role of geographic predictors, and models for jointly characterizing geographic and environmental effects (Rangel *et al.*, 2006; Dormann *et al.*, 2007; Franklin, 2010). The latter include autoregressive methods, generalized linear mixed models (GLMMs), and generalized estimating equations. A problem is that it is always difficult to distinguish between geographic and environmental effects using the observational data typically available for SDMs. Models fitted to only geographic predictors – for

Figure 2 The relationship between niche (environmental) and biotope (geographic) space, showing (i) a point in environmental space might have more than one realization in the biotope (point C); (ii) a point in environmental space may not occur in the biotope (point D); (iii) points can be nearby in environmental space and far apart in the biotope (A and B); (iv) a model can create patterned predictions due to spatial autocorrelation (patterning) in the biotope realization of environment.

example, to two-dimensional trend surfaces with latitude and longitude as axes – have been shown in some studies to predict as accurately as environment-based models within sampled regions. This is not surprising if species have severe dispersal limitations and occur in highly fragmented landscapes, or if suitable maps of relevant environmental predictors are not available. It does not mean that environment is not important, merely that the signal is hard to determine from geographically restricted samples and can be swamped by geographic factors. A model with only geographic predictors is not useful for predicting to new times or places.

The Shapes of Species Responses to Environment

According to niche theory, the shape of the curve relating species abundance or fitness to an environmental gradient (**Figure 1**) is unimodal (hump-shaped) and describes upper and lower tolerance limits as well as an optimum (central tendency). Although early work depicted response curves of species in a community as Gaussian with breadth limited by competition, real communities do not usually show this idealized pattern. However, species in a community often do show a pattern of turnover along a gradient, and this pattern is assumed in many multivariate community analysis methods. There is empirical support for skewed or even nonunimodal response curves where species reach physiological limits of growth and survival at the harsh end of a gradient or are limited by competition at the ameliorative end (or both). Research in this area has focused on estimating response curve shape, niche breadth (specialization), and marginality (the location and density of optima).

It is also widely acknowledged that response curves can take almost any form under different circumstances. For example they might be linear if there is a strong limiting factor, or if only a portion of the gradient is sampled. They might be multimodal in the presence of a strong competitor. They may be complex if there are interactions among variables in the high-dimensional environmental hypervolume, especially if predictors used in modeling are surrogates or proxies for the true resource gradients. If complex response functions are fitted, they can be evaluated in terms of possible causes (incomplete sampling of the gradient and so forth) and implications for use of the model (especially if it is to be used for projection). Unbounded response curves – for example, a positive linear or monotonic response to a temperature variable – might give nonsensical projections – for example, the distribution of climatically suitable habitat under a scenario of global warming.

Geographical Models and Theory for Predictor Variables

Even though modern uses of SDM rely as much on conceptual models of geographical data as on ecological theories, this relationship to geographical data models is less well articulated in the SDM literature. There are two contrasting conceptual models used for representing geographical data (Goodchild, 1994). In the “field” view, the precise value of geographical variables can be measured at any location, and geography can be represented as a multivariate or vector field.

Although this is a useful framework for many types of modeling, it does not easily accommodate all geographic phenomena that interest spatial scientists. In the contrasting “entity” view, geography is represented as empty space containing various discrete objects or features (entities), such as mountain peaks, atmospheric low-pressure troughs, fire scar perimeters, or species occurrences. In SDM, one is often accommodating both an entity view of species abundance or occurrence and a field view of environmental predictors, as well as developing models that represent species distributions as a field, either continuous or discrete, of occurrence probability or habitat suitability. Because complex phenomena such as habitat suitability or species richness can never be represented precisely in digital geospatial databases, geographic representations of model error or uncertainty are particularly important for SDM.

There are also some conceptual or theoretical frameworks available to guide the choice of environmental (abiotic) factors affecting species distributions, so we know generally what kind of GIS data we should be looking for. Mackey and Lindenmayer (2001) describe the primary environmental regimes of light, water availability, heat sum, and nutrients, and they outline a spatially nested hierarchy of processes controlling their distribution for terrestrial environments – from global distributions of solar radiation (controlling climate) and lithologies of the geologic substrate, to the local topography moderating heat and moisture patterns at the mesoscale, and finally plant canopies altering those patterns at the microscale. Although this framework has been applied most effectively for plant species, Mackey and Lindenmayer posit that it applies to all types of organisms. A different tradition in wildlife ecology describes the factors determining habitat suitability (for animals) as access to food, water, and cover (nest sites, predator avoidance). The spatial hierarchy described suggests that SDMs using only broad-scale predictors, such as climate factors that vary slowly in space, are likely to capture the broad-scale features of species distributions – for example, ranges – but not the finer-scale aspects of habitat suitability as determined by variables such as terrain and land cover for terrestrial species, nutrient availability for marine species, and flow rates for freshwater species (*see* Environmental Data).

In a Perfect World

We present a hypothetical example to sketch out idealized modeling approaches and provide a reference point for dealing with typically available data (in the real world). Imagine a species of cypress pine, *Cupressus chimera*, that is easily distinguished from all other species and always found if an occupied site is visited. This species is endemic to Uruguay and Brazil, has had opportunity to disperse to all suitable habitats within South America, and tends to be competitively superior to other local trees. Surprisingly, its habitat has been undisturbed by humans or historic events, including volcanic eruptions, landslides, and fires. A team of ecologists wanting to understand its distribution and its varying density across the landscape has time and resources to gather much data. They start by talking to experts and gathering available information on the environmental correlates of related species. They

familiarize themselves with the environmental gradients in the region and gather relevant GIS data. They are interested in topographic, substrate, and climatic effects on its distribution and decide to model the whole distribution with 250-m $\times$ 250-m grid cell sizes. Their climate scientist colleagues say that climate could conceivably vary at that resolution in this region. Soil scientists have unusually comprehensive data on soil depth, fertility, and pH at that resolution. Terrain experts have a 30-m digital elevation model of the area from which they can calculate relevant attributes including slope, aspect, and topographic wetness indices. They prefer to calculate these at fine scales because these best represent terrain processes but have agreed to summarize them to 250 m.

The ecologists plan their fieldwork. They choose four major gradients of temperature, rainfall, soil fertility, and hillslope position and aim to sample representatively across those while ensuring that they cover all geographic regions. They plan to visit 500 sites and, in 250-m $\times$ 250-m quadrats, record the abundance of *C. chimera*. They first conduct a pilot study to ascertain the environmental limits of the cypress. They will sample a little beyond these, but not extensively so – they do not want to waste time sampling totally unsuitable habitat. They choose their 500 sites (ensuring a minimum distance between them of 1 km), take geographic positioning systems (GPSs) to the field, and visit every site regardless of its distance from roads.

Once ecologists are back in the office, the modeling begins. First, the GIS data are prepared using models and data summaries that ensure the predictor information is relevant to the species – for instance, the rainfall data are summarized to emphasize water availability in the driest months because the species is sensitive to water stress. Collinearity between the predictors is assessed and dealt with. Checks of the species data reveal they are Poisson distributed, so the ecologists decide to use Poisson regression models. In a first exploratory phase of model building, boosted regression trees are used to reveal important predictor variables and interactions between them. No substantial interactions appear. Generalized additive models (GAMs) are used for final model fitting, and confidence intervals are estimated. The model fit is assessed, and the residuals are tested for SAC. The ecologists summarize the models, including the selected variables, fitted functions, and predictions. They discuss the results with experts and iterate the models a few times, testing the effect of new predictors and exploring the leverage of certain unusual observations. Since the final model is to be used to understand the correlates of distribution and to predict within the sampled regions, it is documented with attention to interpretation of the fitted functions and cross-validated evaluations of its predictive ability using deviance, correlation, and root mean square errors for statistical summaries. The predictions are presented as means with upper and lower 95% confidence intervals.

Reality Check: Typical Data

Planned data collection such as that just described brings benefits and is a worthwhile investment. However, most modelers are faced with less than ideal data or much more complex real-world situations, so now we move to the typical challenges of modeling with available resources. We should

note, though, that a dataset is not a fixed entity. One might start to model and use the initial results but design a process of collecting important missing data in parallel with achieving other goals. Relevant key terms for following these recently emerging research topics include “biodiversity survey costs and benefits,” “adaptive surveillance,” and “decision theory.” More broadly, the task of the species modeler is to look at the data as realistically as possible, to understand the models and their underlying assumptions, to think through the aims and priorities of the modeling, and then to do as good a job as possible with the data at hand. Better to find that the data are inadequate to the task and report as much than ignorantly fit a model and assume all is well.

Species Data

In a SDM, observations of the species form the response – that is, the dependent variable whose variation might be described by the predictors. For a single species, these can be counts, cover-abundance estimates, or presence-absence or presence-only records, and modeling and validation methods exist for all these response types. In this section, it will become clear that there is a strong interplay between features of the species data and the modeling method because many variations on methods are developed for dealing with the realities of data.

Sample Characteristics

The hypothetical ecologists gathered 500 records across major environmental and geographic gradients. Sample size is important because the number of samples dictates whether the response to environment can be modeled in all its complexity, especially when there are many predictors. Few samples will only allow the strongest trends to be identified. Even though

some algorithms might be more robust than others to small samples, no method can “invent” information that is not present in the data. If modeling rare species or small datasets (e.g., less than 30 sampled sites; or for presence-absence data, less than 30 records of the rarest class), it is worth reading the literature on what can be done with small sample sizes.

Covering the main gradients in the region achieves several things (Cawsey *et al.*, 2002). It ensures that sampling is unbiased and representative of the region. It also provides information to the model about the shape of the species response (the “fitted function,” Figure 1) across varying environments, and for endemic species can allow upper and lower thresholds and optima to be identified. Albert *et al.* (2010) explore a range of sampling designs tailored to specific questions that SDMs might address. If a species’ habitat extends well beyond the environmental limits of a sample (i.e., only a portion of its range has been sampled), the model fitted to the sample might represent the current distribution of the species in that region well enough but using it in applications requiring extrapolation is likely to be problematic. This sort of partial sampling of ranges is common – for instance, when survey data from a particular geographic region are used to model all species that occur in the region, or when fisheries data are used to model all recorded species including bycatch species. Uneven distributions of samples are also common in citizen science programs (e.g., Figure 3), and indications of data support for the model (or perhaps the minimum resolution at which predictions provide useful information) can be useful.

SDMs assume that each sample is independent, meaning that each brings new information to the model. This is most often violated in datasets compiled from several sources, in

Figure 3 The 107,000 unique locations (gray dots) for observations in the online citizen science project, eBird. Restricted to data collected across the conterminous US from 2004 to 2009.

which it is common to find replicate records at one location or very dense local sampling. If the available data include replicates and dense clusters, it is best to consult the literature for appropriate methods for cleaning them or modeling them. Increasingly, tools are becoming available for screening and cleaning data. Samples are also assumed to be random. One common nonrandom sampling design groups records within broader units like regional parks and without sampling any of the intervening habitat. These can be accommodated in generalized linear or additive mixed models or Bayesian hierarchical models, because the units can be treated as random effects. Samples along transects or from fishing towlines can also be modeled with specialized methods, including mixed models or autoregressive models (Aarts *et al.*, 2008).

Record Characteristics

The preceding discussion addressed the general properties of the available sample – its geographic and environmental extent and the independence of records. We now turn to think about the properties of the individual records, though admittedly these two categories overlap. Here we consider the types of data being collected and the relationship between that and what is modeled. Our hypothetical ecologists collected abundance data because they were interested in its variation across the landscape in the context of the communities in which the cypress occurred. In contrast, many datasets comprise records of the observed presence or absence of the species. Usually, modelers are intending to model probability of presence of the species from these data, though some simplify the results to a presence–absence prediction because end users want a map of suitable versus unsuitable habitat. As will be seen in the following section (*see* Presence-only Data), the advantage of presence–absence compared with presence-only samples is that presence–absence samples have clear information on what has been surveyed. However, the meaning of absence can be somewhat unclear and can vary with temporal and spatial resolution of sampling. This can make it difficult to work out what probabilities really mean. For instance, a tree is more likely found in a 1-km² quadrat than a 1-m² plot, a species might be difficult to detect amongst dense vegetation, an annual or cryptic species might only be observed in specific seasons, and a vagile species (e.g., a bird, a fish) might be present at some times and not others. These examples represent different factors (with varying impacts) that influence the record of presence or absence and likewise could affect abundance estimates.

The quadrat or plot size is important in so far as it needs to be well suited to the ecology of the species and the heterogeneity of the landscape. Further, inferences about probability of occurrence are tied to the sampling effort, and a mismatch between the area surveyed and area predicted to (e.g., surveys in 20-m × 20-m quadrats predicted to 1-km × 1-km grid cells) can influence the accuracy of predicted probabilities, particularly if grid cells are not environmentally homogeneous.

Imperfect detection is a more important issue than one might assume given its level of attention to date in the species modeling literature, so here we provide a small focus on it, anticipating that it should rise in prominence in the coming years. The species data that we have so far called presence–absence data are only true presence–absence data if

detection probability is 1. There is growing evidence that detection probabilities for many species are less than 1 – in other words, false absences due to observation errors are common. This means that a model that does not address imperfect detection is modeling some unknown combination of probability of occurrence and probability of detection. Researchers including Royle, Nicholls, MacKenzie, Tyre, Wintle, and Kéry have developed relevant theory and applications. Kéry *et al.* (2010) make a case for calling models that assume perfect detection models of *apparent* distribution. In contrast, a model of *true* distribution would require that two nested processes are explicitly modeled: (1) the ecological process that generates the true distribution of the species, and (2) the observation process that governs probability of detection (Figure 4). Models that deal with imperfect detection are commonly called “site-occupancy” models and are special cases of generalized linear mixed models (Kéry *et al.*, 2010). The key piece of information they require is repeat visits to at least some sites and within a short enough time frame that occupancy can be considered unchanged (i.e., that population closure can be assumed). Garrard *et al.* (2008) address related survey issues for plants. Among the consequences of wrongly assuming perfect detection are that occupancy is underestimated, the estimated strengths of covariate relationships are biased toward zero, and varying detection probabilities are wrongly assigned as varying probabilities of occupancy (Figure 4). With all these problems, one might wonder why explicit modeling of detection problems is relatively rare. In some cases, it may be that ecologists are making an unacknowledged and mostly untested assumption that more sites are better than more visits. This is yet to be broadly assessed, but see Mackenzie and Royle (2005) for tips on allocating survey effort. Kéry suggests that a lack of awareness, the requirement for repeat visits, a current scarcity of easy-to-use software that links to GIS data, and no software implementations taking advantage of modern methods of feature (variable) selection have all contributed to slow uptake. These are changing as we write, and we envisage more attention to this issue in the coming years. We note that imperfect detection also impacts abundance estimates, but these can also be dealt with under the repeat visit–generalized linear mixed model framework.

The third example given earlier, that a species might only be observed in some seasons, can now be seen in the light of the preceding paragraph as an issue of detection. Detection probabilities can vary seasonally, so an obvious way to include seasonal effects is to model them as covariates of the detection probabilities. In the absence of repeat visit data, seasonal effects have also been included as predictors in conventional SDMs. The fact that vagile species only sometimes occupy sites reflects lack of population closure and is technically challenging to model in any framework, with or without detection. Wildlife modelers often approach it by thinking about what defines a *site*, and – rather than strictly define it – model use versus availability (resource selection functions). This puts the focus on where and how the animal uses a territory, rather than on the definition of the territory. Finally, other record characteristics related to locational and taxonomic accuracy are important regardless of the type of data, but covered in the following section.

Figure 4 Simulated data modeled with site-occupancy models and models (GLM; and boosted trees, GBM) that assume perfect detection. Top row: true occupancy and detection (pale yellow high, red low) and their modeled counterparts fitted (“learned”) using a site-occupancy model. Bottom row: true (simulated) observations resulting from the occupancy–detection patterns in the top row with a grid showing sampling locations, and estimated observations learned using the site-occupancy model, the GLM and the GBM. Note that only the site-occupancy model can be decomposed to predict occupancy rather than observation.

Presence-only Data

Presence-only data are now so widely used that they deserve special attention, though some of the issues covered in this section may also apply to other types of data. Two distinct types of presence-only data exist. The first, radio-telemetry data, are common to wildlife studies and addressed in another chapter. What we refer to here as presence-only data are records of presence without accompanying records of surveyed but unoccupied sites, such as records from compilations of observations, checklists, herbarium and museum specimens, and so forth. Presence-only data are increasingly used for SDM because they are often the only source of information on species locations. Their quality and particular characteristics vary according to their source. For instance, fisheries data may be strongly biased to those areas known to be productive and within reach of a port. Museum data as collated in online data repositories such as the global biodiversity information facility (GBIF) are sourced from numerous data providers throughout the world. This makes them a tremendously important source of biodiversity data, but errors, duplications, and biases are inevitable. Their use for species modeling brings particular challenges (Newbold, 2010), including errors and lack of specificity in location, errors and lack of currency in taxonomy, and biases in the sampled geographic or environmental space, the temporal spread of surveys, and the recorded taxa. These violate several assumptions outlined earlier about the types of samples needed for species modeling. Biases are a particularly challenging issue, because – without information on whether the sample is representative

of the species or biased – SDMs will model an unknown combination of survey bias and suitable environments for the species.

Errors including lack of precision can sometimes be corrected, for instance, by working with experts to update taxonomies, using ancillary information to more accurately locate and model records (Niamir *et al.*, 2011), or quantifying uncertainty in location and exploring its effect on model output. Bias is much harder to deal with because it is generally difficult to quantify the biases that exist, but various methods have been suggested, including using information on survey effort for related species (Phillips *et al.*, 2009). The level of research effort being devoted to correcting errors and addressing bias indicates the importance of presence-only data sources for SDM. When using such data it is crucial to be realistic about data quality and apply methods to deal with common errors and biases.

Biotic Interactions and Disturbances

We discuss biotic interactions and disturbances here, between species and environmental data, because they affect the species records but can also be considered predictor variables. Use of SDMs for predicting effects of climate change and invasive species have reinvigorated efforts to include biotic interactions in models because they are clearly one of the ecological realities that will substantially affect the future distributions of species. There is limited scope in correlation-based species distribution

models to deal cleanly with biotic interactions because those interactions have affected the distribution of species data, and there is rarely independent evidence of what would have occurred if those effects (competition, mutualism, facilitation) were removed (but see [Leathwick and Austin, 2001](#), for an exception). In some large, carefully selected datasets, there may be enough information to usefully explore the effects of competition on species abundance. For instance, [Meier et al. \(2011\)](#) used data from 6000 forest plots to model the abundance of European beech in relation to three major competitors. Models, including predicted distributions of the competitors, indicated strong effects of competitors in favorable growing conditions but weakened links in unfavorable environments. Biotic interactions are a fact of nature, and we anticipate ongoing efforts to understand and model these, perhaps most effectively through mixes of correlative and mechanistic models.

Disturbances – recent (fire, land clearing for agriculture) and historic (glaciations, past volcanic eruptions) – also affect distributions, with the temporal scale of the effect varying with the disturbance and the ecological characteristics of the target species. So far these are rarely included as predictors in models due to lack of mapped data, but remote sensing information is likely to promote their use. One advantage of having them as predictors is that conceptually it would then be possible to remove their effect from the modeled distribution where potential distributions are required.

Environmental Data

In our perfect world example, the modelers gathered GIS data describing the environmental gradients in the study area and then summarized them in ways that were relevant to the species. In reality, in spite of growing volumes of geospatial data available for many parts of the world, much of it derived from remote sensing ([Skidmore et al., 2011](#)), these data do not necessarily describe the most proximal environmental factors that limit species distribution and abundance; nor are they always available at scales relevant to the species. Further, detailed knowledge of the proximal factors that limit species distributions is not available for most species. Instead, SDM analyses often model many species (e.g., to determine patterns of biodiversity or conduct and environmental impact analysis), and a common and convenient set of available predictors is used. These predictors frequently include descriptors of climate (and sometimes substrate, terrain, and land cover) in terrestrial settings, hydrology in aquatic ecosystems, and bathymetry, productivity, and sea surface temperature in the marine environment. The challenge in SDM is to develop a set of candidate predictors that are likely to have a proximal relationship to species distributions. This often involves applying a transformation or model, sometimes a complex one, to the mapped variables. In the following sections we discuss relevant variables over a range of scales, recognizing that many local modeling efforts might have access to, or ability to collate, a potentially broad suite of relevant predictors.

Climate

Although it is well known that climate limits species distributions at broad spatial scales, the variables that

climatologists typically measure, and interpolate into maps such as monthly precipitation and minimum and maximum temperature averages (or measures of humidity or solar radiation), are not necessarily the most biologically meaningful factors. For example, in our perfect world example, precipitation during the dry season was known to be a limiting factor for the species of interest. Therefore, in the 1980s, researchers in Australia defined a set of bioclimatic variables for SDM ([Busby, 1991](#)) that are still used today ([Hijmans et al., 2005](#)). These involve transforming monthly precipitation and temperature averages (average is usually defined as 30 years in climatology) into measures of seasonal averages or variation, contrasting the warm and cool or wet and dry seasons. Temperature sums such as growing degree days (above some minimum) and water-balance measures based on calculations of potential and actual evapotranspiration may be even more closely related to the primary regimes of heat and water availability, and for some species the most important parameters might be climate variability and extremes (e.g., frequency and duration of droughts and floods).

Some applications of SDMs (e.g., for exploring macroecological theories) are at coarse resolution and global extent, and these tend to focus on climate variables. For those wanting to model at finer grain, until now the main globally coherent dataset has been the Worldclim variables ([Hijmans et al., 2005](#)) with 19 rainfall and temperature-based variables and a finest resolution of 1-km grid cells. Current efforts are likely to provide a broader suite of variables in the near future. In addition, with so much emphasis on the use of SDM to assess the potential impacts of global warming on ecosystems, it is important for species distribution modelers to understand the data and methods that climate scientists use to interpolate historical climate records, and to appropriately downscale coarse-resolution climate model projections of future climate scenarios.

Terrain

Elevation is either a modeled or a satellite product and is available globally. Elevation per se represents an indirect environmental gradient, correlated with but not directly measuring temperature and moisture regimes ([Austin, 2002](#)). There is rarely a good reason to include elevation as a predictor, since other more proximal variables (such as temperature) are usually available. At any given elevation, terrain strongly modifies the radiation regime and available soil moisture and these effects of slope, aspect, and hillslope position can be modeled ([Wilson and Gallant, 2000](#)). Other elevation-based measures are also useful for some species, including local variation (e.g., ruggedness calculated from standard deviations of elevation in certain windows), compound topographic index (a measure of the water flow through the landscape relying only on topography), and estimates of landscape position (ridge or valley).

Substrate, Soils, and Land Cover

Information on substrate and soils is usually one of the hardest to find in a format and at a scale useful for species modeling. Traditional approaches to soils mapping usually focus on classifications, whereas continuous variables such as soil depth, pH, fertility, and water-holding capacity are more

directly related to species distributions. When continuous soil properties are mapped, they are often available only at coarse scales. Recent focuses on harmonizing soils information globally and on modeling soils characteristics in relation to terrain are likely to produce useful products for species modeling.

Land cover or vegetation type is often an important, or even the only, predictor used in species distribution (habitat suitability) models for wildlife. Vegetation composition and structure are strongly related to habitat use for many species, from butterflies and birds to bears. Land-cover maps, based on remotely sensed and other data, are now being compiled at regional to continental scales to monitor global environmental change, and these data products often include somewhat detailed information about natural vegetation categories beyond simply life form (forest, grassland), for example, for North America and Europe. These large-area datasets, as well as subregional maps of vegetation type and vegetation attributes, have proven useful in SDM. In some cases, remotely sensed biophysical image maps or data products are used directly (without classification) in modeling distributions. These include maps of net primary productivity, leaf area index, canopy roughness, reflectance, greenness indices, and other spectral transforms. Land-use maps show the distribution of human disturbance in the form of land-use change, and fire history maps show the distribution of natural disturbances. Land-cover, land-use, and disturbance maps can be brought into SDM to address, to some extent, biotic interactions (distribution of other species) and community dynamics as affected by disturbance (*see* Biotic Interactions and Disturbances).

It is important to keep in mind that, when using predictors such as soil survey maps, large-scale soil databases, land-cover maps, or vegetation maps, these were produced using protocols, decision rules, methods, and models that are as complex as SDM (in some cases, indistinguishable from SDM – e.g., Ohmann *et al.*, 2011) and so have many assumptions built into them, for example, from the choice of classification system to the resolution or “minimum mapping unit” and the spatial homogeneity of those units. They are often developed to suit multiple needs and may have multiple attributes. In particular, when a categorical (thematic) map is used in SDM, it is necessary to reclassify or transform the categories in ways that are meaningful. If modeling habitat suitability for a forest-dependent bird using a land-cover map as a predictor, it may not make sense to retain dozens of categories of crop type or urban land cover. These use many degrees of freedom, estimating parameters for each category, and are essentially meaningless. A simple quantitative predictor such as forested area within a certain neighborhood could be derived from a land-cover map. As another example, soil or rock-type maps can be reclassified into categories of high, medium and low nutrient availability, or soil series could be grouped into simpler categories such as soil order.

Aquatic Systems

The most sophisticated sets of predictor variables for freshwater systems are based on rivers and streams represented in GIS as a network topology, with each river or stream section between adjacent confluences represented by a unique segment, and the ability to trace up- and downstream to

summarize environments and trace species movements. Environmental attributes including physiographic, bioclimatic, edaphic, land-cover, and disturbance-related variables can be estimated at hierarchically nested spatial scales (e.g., the riparian zone of each segment, its immediate watershed, and its upstream contributing catchment area). These provide biologically relevant data for predicting distributions.

In marine systems, depth is an indirect proxy for several proximal predictors: temperature and its variability, salinity, light, pressure, and the availability of elements (e.g., calcium). Marine species distributions are also affected by ecosystem productivity (e.g., as quantified through measures of chlorophyll *a* or zooplankton), by tides and currents, and by dissolved oxygen. Gradually, more globally complete sets of marine data are becoming available (e.g., Tyberghein *et al.*, 2012), and various countries are developing their own regional datasets at higher resolution.

Multicollinearity of Environmental Predictors

An important issue requiring attention is collinearity between variables – that is, the statistical correlation between two or many variables (Dormann *et al.*, 2012). Collinearity is common in large sets of predictors because several variables might be representing the same underlying but unknown latent (unobserved) and most proximal variable. Collinearity may not be problematic if the main use of the model is for prediction within the range of the sampled data (interpolation). In these cases, selection from a large candidate set of variables might be successful, particularly with large numbers of species records and methods with variable selection procedures that are robust to collinearity. However, prediction to new times or places will be problematic if the correlation structure changes because the model might have selected a correlate of the true variable, whose relationship with the true variable is not maintained in the new prediction space. The fundamental problem is that statistical models identify correlation, not causation, and there is no straightforward way to decide which variables to focus on and which to ignore. Many datasets include collinear variables – for example, the many bioclimatic variables available in datasets such as Worldclim are often highly correlated. It is tempting to use all predictors at hand and “let the model decide” which are important through model selection procedures when there is not strong theory predicting the most proximal factors limiting the distribution. However, it leads to more interpretable and parsimonious models, and hopefully more transferable (useful for projections) ones if a subset of predictors can be chosen based on the literature, expert opinion, or exploratory data analysis.

The Models

Generally in SDM, the response variable is a measure of species occurrence or abundance, and there are multiple candidate predictors describing the physical environment that are thought to be important limiters of species distributions. SDM is thus a supervised classification or statistical learning problem (*sensu* Hastie *et al.*, 2009).

A continuum of approaches are available for supervised learning. At one end of the spectrum are those approaches that have high bias (make assumptions about the form of the relationship between response and predictors) and low variance (tend to make robust predictions when applied to new data). These are sometimes referred to as *model-driven* or *parametric* methods. At the other extreme are those approaches that have low bias but high variance, which some call *data-driven* or *nonparametric*. Although it can generally be said that machine learning methods are nonparametric and data driven, and statistical methods are parametric and model driven, this distinction is being increasingly blurred by the regularization methods used in machine learning to reduce variance, and nonparametric methods used in statistics to reduce bias, such as the curve-fitting used in GAMs.

The predominant statistical framework that has traditionally been used for SDM is that of generalized linear models (GLMs) in which the many predictors are environmental variables (X) and the single response variable (Y) is a measure of species occurrence or abundance (or another biodiversity measure). *Generalized* means that the model can cope with nonnormal error distributions of the response variable. For example, in SDM if Y is binary (species presence or absence), then the binomial distribution is used; if Y is a count, then Poisson errors might be appropriate. The GLM can be expressed as

$$g(E(Y)) = LP = \hat{\beta}_0 + \sum_{j=1}^p X_j \hat{\beta}_j + \varepsilon$$

where the predictor variables (X 's) are combined to produce a linear predictor, LP , and the expected value of Y , $E(Y)$, is related to the LP through the link function, $g()$. The link function describes how the mean of Y depends on the linear predictor, and a variance function describes how the variance of Y depends on its mean for any particular distribution from the exponential family. The *linear* part of GLM means that the models are linear functions of the parameters, not necessarily of the independent variables. GLMs have the flexibility to characterize nonlinear responses to a predictor by adding terms to the linear model such as polynomial terms (to characterize unimodal responses) or piecewise linear terms (to estimate threshold responses). Categorical predictors can be incorporated as dummy variables, and interactions can be specified. GLMs are the basis for an extended set of models, including GLMMs, geographically weighted regression, and spatial autoregressive methods that can deal with all sorts of complexities of real datasets (*see* Species Data).

GAMs are closely related to GLMs and tend to have lower bias but higher variance because the coefficients of the GLM (β s) are replaced by a function, f , typically some kind of a smoothing spline whose complexity is controlled by the degrees of freedom allocated to it. GAMs are convenient for fitting skewed response curves or any form of nonlinear response because the shape of the function in the GAM is data driven and not prespecified. For both GLMs and GAMs decisions are required about how to select the final model – including the complexity of the fitted functions and whether to select subsets of variables. Ecologists have paid much attention to model selection based on information criteria such

as Akaike's Information Criterion (AIC), but there are a broad suite of possible approaches including shrinkage of parameters, L1-regularization, and so on (Hastie *et al.*, 2009).

With changing emphasis on what is required of models and rapid advances in computing power and machine learning and data-mining algorithms, methods have proliferated. Examples include classification and regression trees (decision trees) and ensembles of them, artificial neural networks, maximum entropy methods, genetic algorithms, and support vector machines. Each has particular strengths and weaknesses. For instance, decision trees use recursive binary splits (a hierarchical splitting procedure) to partition the predictor space into rectangles within which the response is most homogenous. Their tree-like structure identifies interactions and easily handles categorical predictors and threshold responses, and it represents information in a way that is intuitive and natural to visualize. They can be applied to binary, continuous and categorical responses. However, there are some drawbacks: decision trees tend to vary with the sample (i.e., they have high variance) and do not characterize linear or smooth responses very well. Ensembles of trees (including bagged trees, boosted trees, and random forests) overcome these limitations and are increasingly used. They have strong predictive capacity and reliable variable selection, and they can fit complex responses. Several can be applied to a variety of types of species data (e.g., presence-absence, count) similar to regression models. Intriguing recent applications of tree ensembles address imperfect detection (Hutchinson *et al.*, 2011) and spatial and temporal variations in bird-habitat associations (Figure 5 and Fink *et al.*, 2010). Currently, machine learning methods tend to be viewed as fitting more complex models and therefore are useful for prediction but perhaps not so well suited for applications requiring smoother models (prediction to new times or places). This is an oversimplification, and it is likely that the breadth of machine learning methods will continue to expand and find useful applications in species modeling.

Presence-only data tend to be modeled both with specialized methods and with adaptations of methods applicable to presence-absence data. Multivariate distance and envelope methods are also sometimes called *profile* methods (Pearce and Boyce, 2006) and characterize habitat suitability in terms of descriptors of the environmental conditions where species are observed to occur. The descriptors can be ranges (minimum and maximum), medians, means, or multivariate distances in environmental measurement space. Those methods based on ranges are sometimes called *envelope* methods, and they were among the earliest approaches used in SDM. Multivariate distance measures are widely used in community ecology and other fields, and they can be used to classify new observations in terms of their distance in environmental hyperspace from a descriptor of the species occurrence locations – for example, mean centroid or nearest neighbor. Distance measures that have been used in SDM include Gower and Mahalanobis. Mahalanobis scales the difference between an observation and the mean vector for species occurrences by the covariance between predictors, thus making the distance measure independent of the scales of the predictors. However, Mahalanobis gives all predictors equal weight and cannot be used with categorical predictors. Nonetheless, distance-based methods appear to have

Figure 5 Example of use of a complex model for ecological inference. Here a machine learning method adapted for dealing with spatial and temporal variation in species–covariate relationships (Fink *et al.*, 2010) is used to predict the distribution of indigo bunting (*Passerina cyanea*) based on ~600,000 presence–absence records at 107,000 locations across 5 years (Figure 3) and covariates, including remotely sensed habitat classes. The map shows the predicted distribution on 20 June, and the plots show trajectories of predictor importance in two regions (green polygons) for two example habitats: deciduous forest (red) and cultivated crops (blue). In the northeast (region 1), foraging patterns shift from the forest (targeted on arrival and subsequently for breeding) to the crops (important during fall migration). In comparison in the core of the bunting’s breeding distribution (region 2), the species commonly occurs in most habitats so there is much less variation over the season and no dominant predictors (note the smaller predictor importance values) as in the northeast.

a strong and continuing tradition of use in wildlife management studies (e.g., Hellgren *et al.*, 2007).

On the machine-learning side of things, applications of maximum entropy theory (MaxEnt) and genetic algorithms (GARP) have been widely used for modeling presence-only data, primarily because they provided interface-driven software that made it easy to deal with common data types. In common with adaptations of regression methods, these methods compare the environments occupied by the species with those in a selected region. Environments in those regions are characterized by taking background samples (also called *pseudo-absences*, though the latter term has a range of subtly different interpretations; Phillips *et al.*, 2009). Details of how each approach works and performs are described in recent publications.

Bayesian methods are also increasingly used for species modeling, particularly for more challenging modeling problems where the flexibility of the Bayesian approach allows realistic specification of the problem and useful ability to update models as new information becomes available. Recent texts by Michael McCarthy and Marc Kéry introduce these methods to ecologists.

Although the modelers in our perfect-world example evaluated predictions of species abundance using measures of model fit and predictive performance typical for continuous response variables (e.g., root mean square error), it is worth noting that most SDMs are developed using presence–absence or presence–background data and use performance measures suitable for binary predictions (reviewed in Elith and Leathwick, 2009b; Franklin, 2010). These include threshold dependence measures such as the area under the (receiver operating characteristic) curve (AUC) and threshold-dependent measures such as the kappa coefficient of agreement (where

the threshold is a value applied to a probabilistic prediction of species occurrence in order to distinguish presence from absence predictions). Issues of how to set up testing and training datasets in ways relevant to the modeling problem are important, as are evaluations beyond simple “fit to data sample” measures, including whether the model and its predictions make sense to experts.

Species Distribution Modeling for Other Biodiversity Measures

The general modeling approach of SDMs can be applied to a range of biodiversity attributes. For instance, community diversity, community composition, community type, and functional group distribution have all been modeled, though species diversity (often species richness) has received most attention. Various theories of species diversity hypothesize the driving factors to be energy availability, which can be indicated at broad scales by ecosystem productivity or potential evapotranspiration (Currie, 1991) or environmental heterogeneity (Pausas *et al.*, 2003). Two distinct approaches have been used: calibrating a model using species richness as the dependent variable versus developing SDMs for each species in an area and adding their distribution maps to estimate richness per grid cell (a stacked SDM approach). Using the first approach, species richness is increasingly being predicted directly from remotely sensed variables or indices related to productivity, water and nutrient status, and vegetation structure and phenology (e.g., net primary productivity, greenness indices, surface temperature, and image texture). Essentially, these are biodiversity models with

only one or a few predictors that are exclusively derived from remote sensing data.

Predictive maps of species richness are uninformative about species composition, and often information on community or ecosystem composition is needed for biodiversity assessment and conservation planning (Ferrier and Guisan, 2006). Individual SDMs have been stacked together (predict species distributions first, then classify communities), and community or ecosystem type has been modeled as a categorical dependent variable (classify, then predict). Composition has also been modeled by estimating species turnover among sites – for example, using a form of matrix regression (generalized dissimilarity modeling) or other approaches based on multivariate distance.

Other frameworks for summarizing general species attributes or distributions are also relevant to understanding and managing biodiversity. Plant life forms or functional types form the basis of most mechanistic dynamic vegetation models, and so SDMs developed for functional types may be useful for evaluating the impacts of environmental change on biodiversity. Biogeographical regions have also been defined, based on SDM-like models, at global (Kreft and Jetz, 2010) and regional (Leathwick *et al.*, 2011) scales.

Predicting to New Times and Places

Although the original uses of SDMs were for understanding ecological data and predicting within sampled regions, predictions to new times and places have now become a strong focus. SDMs are inherently poorly suited to such applications because they are based on correlations (not causal relationships) estimated within a training region that is not necessarily related environmentally or ecologically to the new conditions of interest. Their basis in realized distributions also creates difficulties for useful projections elsewhere (Colwell and Rangel, 2009; Sinclair *et al.*, 2010). Nevertheless, researchers persist with these applications because information is required and so far there are few alternative practical methods for producing it. Two main scenarios are climate change and invasions. These are high-priority research areas because both can have immediate and long-lasting detrimental effects on biodiversity and both are costly to mitigate.

For climate change applications, SDMs fitted to current environments are projected forward to new climates predicted and downscaled from global circulation models. The early simple applications of these models now seem relatively naïve, and researchers are exploring new avenues by including biotic interactions; defining the ability of species to migrate – often across fragmented landscapes – with changing climates; exploring the realities of microclimates that might provide refugia, including realistic fine-scale predictors that affect the local complexity of species distributions; controlling the shapes of the fitted functions; identifying where climates are novel; using predictors suggested by ecophysiological models as important constraints to persistence; and linking the SDM outputs to process-based models that explicitly focus on birth, death, dispersal, spread, and other population processes. Uncertainty across modeling methods and alternative GCMs and emission scenarios has also been explored. These

advances may help to make predictions more realistic, but they cannot overcome the inherent problem that a model based on correlations does not and cannot identify causes, nor can one based on realized records predict fundamental niches. Perhaps the best way forward is to carefully define what ecological and data characteristics make species more likely amenable to successful prediction, to keep collecting biological information so models are as well informed as possible, and to progress understanding and visualization of uncertainties and their integration into decision making so these can be properly understood and accounted for by policy makers.

Another “across-time” application is prediction to past climates. Paleodistributions are hindcast using paleoclimate maps based on reconstructions or models typically available only for key time periods such as the last glacial maximum and mid-Holocene (e.g., from the Paleoclimate Modeling Intercomparison Project). Paleodistributions modeled from SDMs have an advantage over future distributions predicted from climate scenarios in that they can be evaluated with paleodistribution data (fossils, pollen, molecular phylogeographies), albeit these data may be sparse in time and space. This approach has recently been used to compare alternative hypotheses of allopatric diversification, identify locations of past climatic refugia, estimate postglacial migration rates, and even identify likely postglacial migration pathways, for plants, vertebrates, and invertebrates in both the tropics and temperate–boreal zones.

SDMs are also used outside their training range for predicting the potential distribution of invasive species. Also called *pest risk mapping* and *climate matching*, these models are usually of interest in biosecurity for identifying species likely to become pests, guiding monitoring programs to areas most likely to be infested, and providing a basis for sharing costs of containment or eradication between jurisdictions. Again, there is a mismatch between what is required (a prediction of the fundamental niche of the species that could be occupied in the invaded range if the species was able to spread everywhere and if biotic conditions were suitable) and what is possible with a SDM. A major issue is that the native range of a species might only represent part of its fundamental niche, so models are uninformed about the ability of the species to persist in climates outside of those encountered in the native range. Added to that, the usual problems with incomplete and biased species data, imprints of biotic interactions, and lack of knowledge about the true predictors of distribution make the task a difficult one. At the time of writing, a much stronger appreciation of the technical problems is developing make we anticipate advances in tools for diagnosing and reporting likely problems and methods for controlling models perhaps through integration with expert knowledge. Invasive species are also modeled with partially mechanistic models, and in the invaded range, SDMs have been combined with various types of spread models (Iverson *et al.*, 2011).

Conclusion

Species distribution models are statistical models of species–environment relationships based on species location

(abundance, occurrence) data and measures of environmental variables limiting species distributions. They are usually used to make spatial predictions. SDMs have been developed for marine, terrestrial, and freshwater species at a wide range of scales. In spite of the growing availability of bioinformatics databases and geospatial data, the accuracy and usefulness of SDMs are often limited by data availability, though limitations can be addressed through additional survey and sampling, as well as geospatial data processing.

There are hundreds of published SDM studies, and the number is growing. Until recently, these studies often emphasized the technical issues of modeling methods and model evaluation. Tremendous progress has been made in statistical and machine learning methods, advances that tend to blur the distinction between them. Increasingly, SDM studies now emphasize the application of SDM to problems in environmental assessment, forecasting, and macroecology. SDM is a powerful tool for biodiversity assessment and conservation planning. SDMs are used to project species distributions to novel times and places because of the overwhelming importance of questions regarding the impact of environmental change on biodiversity. Based on correlations and not causal mechanisms, SDMs are inherently poorly suited to making projections under novel conditions. Combining SDM with other data and approaches, such as spatially explicit models of population and community dynamics, may improve forecasting and impact assessment of environmental change at larger spatial scales.

The particular application of SDM, as well as the characteristics of the data, must determine what is emphasized when modeling. Species detection probability, environmental limiting factors, SAC, sample size, sample bias, scale, disturbance, biotic interactions, and demographic processes will vary in their importance among species and datasets and depend on the intended purpose of the model. Thus, understanding the data, the question, the particular features of different model types, and how to assess errors and uncertainties is part of the art of fitting and evaluating species distribution models.

Glossary

Key innovation A property of a species that promotes the process of speciation.

Molecular phylogenies Phylogenies constructed from comparisons of homologous genetic material.

Radiation All the species descended from a single common ancestor; tends to be a speciose group in comparison with others of a similar age.

Reconstructed evolutionary trees Phylogenies linking contemporary species, therefore containing no information about lineages that have gone extinct.

Sister taxa The expression has two uses, according to context. First, from a species perspective, the sister taxon of a particular species is the one with which it had the most recent common ancestor. Second, from the perspective of a node in a bifurcating phylogenetic tree, each daughter lineage gives rise to a set of contemporary species. The two sets are sister taxa with reference to the node.

The Fossil Record and Contemporary Biodiversity

The generation of biodiversity involves, in large part, the origins of species. The fossil record, though notoriously incomplete, provides the most direct evidence for tracing temporal changes in biodiversity, including both the origin and extinction of lineages. Biases in preservation, often confounded with differences in taxonomic interest among paleontologists, mean that much more is known about the history of some taxa than others. For example, May (1996) points out that while around 95% of fossil databases consist of shallow-water marine invertebrates, most of today's known species are terrestrial, with 56% being insects. At the same time, Benton and Storrs' (1996) analyses suggest that more is known about the fossil history of vertebrates, most of which have been terrestrial, than of echinoderms, which are marine.

Benton's (1993) extensive compilations of stratigraphic incidence records for different lineages reveal the extent of well-known mass extinctions, followed by the subsequent regeneration of biodiversity. The rises in biodiversity that follow mass extinctions are presumably a consequence of the exploitation of (and speciation into) vacant niches. Also it is clear that the demise of some radiations is accompanied or followed by the rise of others; dinosaurs and mammals are cases in point. The causes of such complementarities have been hotly debated for many years. Similarly, there are times when one radiation is accompanied by, or shortly follows, another. The angiosperm plants are a massive radiation, as are the beetles. Cause and effect have been firmly suggested: the radiation of angiosperm plants provided a new set of niches into which beetles could speciate (Farrell, 1998). Arguments such as this are frequently anecdotal in that they involve post hoc explanations that require further testing, which often proves very difficult. For example, while the angiosperm plant radiation can explain about one-half of the species number in the beetle radiation (there are about 300,000 known beetle species), the other half remains unexplained. As Barraclough

et al. (1998) point out, the angiosperm radiation does not explain the large radiation of 50,000 mainly carnivorous and fungivorous beetle species in the Cucujoidea or the equally large radiation of predatory beetle species in the Staphylinoidea.

Reconstructed Versus Real Evolutionary Trees

The reasons for the origins of contemporary biodiversity are becoming better understood, largely as a consequence of advances in molecular genetics. Gene sequence analysis has become routine in many laboratories, and sequence data are deposited in openly accessible data banks. When equivalent sequences are available from different species, phylogenetic trees can be reconstructed. If a molecular clock has been operating, these trees show when in relative time any pair of species last shared a common ancestor. When the molecular clock can be dated, the trees can be calibrated in real time. Such phylogenies show the relationships among contemporary species, and contain no explicit information about extinct lineages. However, the structure of such trees can be used to demonstrate which evolutionary models are more likely than others to explain the origins of biodiversity in particular taxa.

When a model-based approach is used to analyze the origins of biodiversity, it soon becomes apparent how easily intuition can lead us astray. For example, the tree reproduced in Figure 1 shows the relationships among contemporary salamander species from the genus *Plethodon*. The branching rate in the tree seems to have increased recently. This, however, does not necessarily mean that the net rate of speciation has increased. The simplest model to describe the generation of biodiversity is a constant-rates model in which the rate of speciation (lineage splitting) and the rate of extinction have been the same in all lineages at all times since the root of the tree. Obviously the rate of speciation will have been greater

Figure 1 A phylogenetic tree reconstructed from genetic data showing the relationships among salamanders of the genus *Plethodon*. D is Rogers' genetic distance. The phylogeny reconstruction assumes a molecular clock, meaning that nodes are placed approximately correctly in relative time. No absolute timescale is available because the rate of ticking of the molecular clock is not known with precision.

than the rate of extinction, or the tree would not have grown. Under such a model, if the rate of extinction is zero, a lineages-through-time plot based on the relationships among contemporary species would be a straight line with a slope, λ , the speciation rate. As the rate of extinction (μ) increases, so does curvature of the line upward toward the present (Figure 2). This means that the plethodontid salamander tree, with its increased branching rate toward the present, is representative of a phylogeny generated under a high rate of extinction relative to speciation. Of course, speciation and extinction rates could have been changing through time, but the simple constant-rates model is sufficient to explain the data. If we accept this model, then it is also possible to estimate speciation and extinction rates or, more usefully for conservation biologists, the net rate of speciation ($\lambda - \mu$) and the danger of a clade going extinct (μ/λ) (Figure 3). Similar analyses have been carried out for diverse taxa, including primates, carnivores, *Drosophila*, and birds.

Biodiversity cannot increase indefinitely. Eventually, any adaptive radiation will run out of niches to occupy and net speciation rates will decrease. Such an effect is apparent when Sibley and Ahlquist's (1990) molecular phylogeny of birds is analyzed as a lineages-through-time plot (Figure 4). Instead of the line steepening toward the present, there is a general leveling off. In the absence of fossil material, which is relatively sparse for birds, it is not possible to say whether, in fact, speciation rates have decreased through time, extinction rates have increased, or both. Sibley and Ahlquist's phylogeny is one of the earlier molecular phylogenies and is based on

Figure 2 The expected forms of an actual phylogeny (top line) and a reconstructed phylogeny (bottom line) produced by a birth-death process, in which the constant per-lineage speciation rate (λ) is greater than the constant per-lineage extinction rate (μ). Note that the two curves would be superimposed if the extinction rate was zero. The initial steep slope of the line for the actual phylogeny is a consequence of only a sample of phylogenies surviving to the present and those are likely to be the ones that got off to a flying start. Note also that as μ increases from zero toward λ , so does the change in slope of the reconstructed line, so that a steep upturn describes a phylogeny where μ is high in comparison with λ . Reproduced from Harvey PH, May RM, and Nee S (1994) Phylogenies without fossils. *Evolution* 48: 523–529.

Figure 3 Contour plot of the likelihood surface for the *Plethodon* data (Figure 1). The maximum likelihood estimate, the peak of the surface, is marked by an X. The lines surrounding it approximate to the 90, 95, and 99% confidence limits, respectively. Reproduced from Nee S, Holmes EC, May RM, and Harvey PH (1995) Estimating extinction from molecular phylogenies. In: Lawton JH and May RM (eds.) *Estimating Extinction Rates*, pp. 164–182. Oxford, United Kingdom: Oxford University Press.

Figure 4 A lineages-through-time plot for the molecular phylogeny of birds. All families are represented, that is, all lineages that were present about 45 million years ago and have left descendants in the present day. Accordingly, we should not expect the leveling off of the curve under a constant-rate process: either speciation rate has been decreasing over time or extinction rate has been increasing. There is no evidence for sharp kinks in the curve, which would provide evidence for mass extinction events. For example, the mass extinction at the end of the Cretaceous about 65 million years ago is thought to have resulted in the loss of about 75% of species in many taxa. Reproduced from Nee S, Mooers AØ, and Harvey PH (1992) The tempo and mode of evolution revealed from molecular phylogenies. *Proc. Natl. Acad. Sci. USA* 89: 8322–8326.

DNA–DNA hybridization data: DNA from different species is annealed, and then heated to dissociate the strands. The more similar that strands are in base composition, the higher the temperature at which they dissociate. More recent studies based on direct comparison of sequences largely support Sibley and Ahlquist's original phylogeny, which, for example, indicated for the first time that the Australian passerines are an independent radiation from other passerines. In addition to many sequence-based studies that lend support for the general phylogeny, one reports a slowing down in the net rate of speciation in eight out of nine genera studied.

If we are to better understand the reasons for the generation of biodiversity, it is critical that molecular phylogenies are properly related to the known fossil record and to our understanding of biogeographic events. For example, the molecular phylogeny of birds reveals two aberrant clades that were speciating at a higher rate when that for others was slowing down. The two radiations resulted in the Passeriformes (seed-eating birds) and the Ciconiiformes (mainly shore-birds). The fossil record of both groups is poor, but it is clear that the radiations occurred at a time when landmasses were warmer and shorelines longer than previously. Though cause and effect may be inferred, the unique events described leave the way open for other possible explanations. One way to strengthen interpretations is to show similar increases in biodiversity associated with the similar environmental changes on repeated occasions. If it could be shown, for example, that bursts in speciation among shore-birds were repeatedly associated with increases in the length of shoreline, it would be less likely that a third unknown environmental factor was responsible for changes in shorebird speciation rates.

Key Innovations, Sister Taxon Analysis, and the Origins of Adaptive Radiations

It is not necessary that increases in biodiversity occur in response to environmental changes: so-called key innovations may evolve that allow the invasion of currently unoccupied niches. Liem (1973, 1980) suggested that one such innovation is responsible for the much higher rates of speciation among cichlid fishes than among their sister taxa. Liem pointed out that a small shift in position of a single muscle attachment ultimately allowed the pharyngeal bones of cichlids to manipulate their prey items while still holding them. As a consequence, the premaxillary and mandibular jaws were freed to evolve along new routes that did not involve manipulating prey. This, the argument runs, allowed cichlids to evolve a whole new diversity of feeding mechanisms and there seems little doubt that the adaptive radiation of cichlids in African lakes, in the face of competition from other fish families, resulted from their evolved diversity of feeding mechanisms. However, the problem of nonreplication occurs: Lauder (1981) correctly pointed out that any other characteristic common to cichlid fishes but that differs from a sister group could, in principle, be the key innovation that resulted in high speciation rates. Conclusions would be strengthened if the same key innovation had been associated with high species diversity in several taxa.

The first example of a statistically supported successful sister group comparison showing a repeated correlate of high species diversity comes from the Mitter *et al.* (1988) analysis of phytophagy, the habit of feeding on vascular plants, among insects. There are considerable barriers to the evolution of phytophagy. Behavioral and morphological adaptations are required to reduce the risk of desiccation, to remain attached to host, and to deal with low-nutrient food. It had been argued that, once those barriers were overcome, the diversity of phytophages would be promoted by both the great diversity of plant species and of plant parts that could not be exploited by a single species, and by the absence of competitors. Mitter *et al.* performed 13 sister taxon comparisons between the numbers of species in a phytophagous clade versus its non-phytophagous sister clade. Since sister clades originated at the same time, they have had identical times for diversification. In 11 of the 13 comparisons, there were more species in the phytophagous clade than in the sister group, and in each of those cases the difference was greater than twofold.

Sister taxon comparisons using newly established molecular phylogenies are beginning to allow the first real statistical tests of many long-standing hypotheses. For example, Darwin (1871) suggested that sexual selection by female choice might increase the rate of reproductive divergence between populations, and thereby increase the speciation rate of a clade. More than a century later, Barraclough *et al.* (1995) tested the idea using Sibley and Ahlquist's phylogeny of passerine birds. Since it is generally accepted that mate choice is responsible for the evolution of sexual dichromatism in birds, Barraclough *et al.* were able to use sexual dichromatism as a measure of the importance of mate choice for a species. In significantly more than 50% of sister taxon comparisons, the clade with the higher proportion of sexually dichromatic species was more speciose than its sister clade, thereby supporting Darwin's suggestion.

Evolution within Lineages: The Comparative Method

It is clear that some characteristics of species can promote speciation itself. But species differ from each other in many ways: morphologically, anatomically, physiologically, behaviorally, and by life history. Making sense of the reasons for that diversity is the job of comparative biologists.

Fewer Causes than Characters

Traits have not evolved independently from each other, and particular characteristics of the environment select for whole suites of traits. For example, among many mammalian orders such as the primates, females tend to be spatially distributed in relation to food resources. If food is in large clumps, females live in large groups, but if food is evenly distributed, females are often territorial. Males distribute themselves in response to female grouping patterns, having been selected to monopolize mating access to as many females as possible. When females live alone in territories, males follow suit and share territorial defense (monogamous, as in gibbons). If females live in small groups, then a single male may be able to defend a group of females from mating access by other males (single-male societies). But if females live in groups that are sufficiently large that they cannot be defended by a single male, then more than one male may join the group (multimale societies). Among monogamous species, the males and females have similar weaponry, such as canines, having been selected equally to defend their territory. In single-male and multimale species, males have enlarged canines relative to females of the species, so that they can defend the group of females, or at least any that are in estrus, against mating access from other males. However, in multimale species, there is always the potential for females to be mated by more than one male; males in such species have markedly enlarged testes as a consequence of selection to produce more sperm per ejaculate, thereby increasing the chances of success in sperm competition. Males of monogamous and single-male species are not subject to selection for sperm competition. Here, then, the distribution of resources influences differences in social behavior, weaponry, and testes size. Indeed, if we know a male primate's testes and relative canine sizes, it is possible to say whether he belongs to a monogamous species (both small), a single-male species (large canines, small testes), or a multimale species (both large).

Identifying Independent Evolutionary Events

As mentioned in the previous section, there are many fewer explanatory factors than there are variable traits across species. How do we identify the factors that are responsible for the patterns of biodiversity that we see today? Species may share traits in common for two evolutionary reasons: they inherited them from a common ancestor or their ancestors independently evolved the traits. Closely related species share more traits through common ancestry, whereas more distantly related species share more through convergent evolution. This does not necessarily mean that traits cannot evolve rapidly in response to selection. For example, when a new niche appears, the species to successfully invade that niche is most likely to be

one that came from a similar niche elsewhere. Very minor changes in phenotype may be sufficient to adapt the new species to its new home. However, the fact that closely related species are subject to similar selective pressures does mean that cross-species correlations can be misleading. For example, in a sample of vertebrates, we might find that those with feathers laid eggs while those with fur gave birth to live young. If the sample contains just birds and mammals, we should be wary of saying that the two sets of characters had responded to the same selective pressure. The way forward is to identify evolutionary independent origins of traits and niche occupancy. For example, we know that on many separate occasions bright coloration among insects has evolved together with distastefulness to predators. Because the two traits seem to have evolved in concert, and there is good reason to expect distasteful prey to advertise the fact to predators, we are more confident that they are part of the same adaptive complex.

For continuously varying characters, such as body size, a particularly elegant technique was developed by Felsenstein (1985) that allows comparative biologists to partition out independent evolutionary change and seek correlated evolution among traits. The key realizations are (1) that differences between each pair of sister taxa in a phylogeny evolved independently, and (2) likely ancestral character states could be estimated if characters had evolved according to a Brownian motion model of evolution. To determine whether characters had evolved independently of each other, it is simply necessary to plot sister taxa differences against each other. If one

Figure 5 The comparative method of independent contrasts. Comparisons d1, d2, and d3 are independent of each other under a Brownian motion model of character evolution. Reproduced from Harvey PH and Pagel MD (1991) *The Comparative Method in Evolutionary Biology*. Oxford, United Kingdom: Oxford University Press.

character evolved independently of another, differences between sister taxa would not be correlated (Figure 5).

An example of the use of independent contrast analyses is Kelly and Woodward's (1995) analysis of the correlates of variation in carbon isotope composition ($\delta^{13}\text{C}$) among plant species. Three cross-species correlates of $\delta^{13}\text{C}$ had previously been identified: altitude, latitude, and growth form. When the data were analyzed using phylogenetically independent contrasts, the correlation with latitude dropped out, and when altitude was controlled for there was no correlation with growth form. Alternative interpretations of the reasons for species differences in $\delta^{13}\text{C}$ were thereby reduced in number. Indeed, it was concluded that differences in atmospheric composition (CO_2 and O_2 partial pressures) may be sufficient to explain observed differences in carbon isotope composition.

Glossary

Biodiversity/biological diversity Species, genetic, and ecosystem diversity in an area, sometimes including associated abiotic components such as landscape features, drainage systems, and climate.

Diversity indices Measures that describe the different components of biodiversity, such as species richness (alpha diversity), beta and gamma diversity, endemism, and higher taxon richness.

Ecosystem diversity Diversity of habitats, ecosystems, and the accompanying ecological processes that maintain them.

Endemism State of a species or other taxon being restricted to a given area, such as a specific habitat, region, or continent.

Flagship species Charismatic or well-known species that is associated with a given habitat or ecosystem and that may increase awareness of the need for conservation action.

Genetic diversity Genetic variety found within or among species; this diversity allows the population or species to adapt and evolve in response to changing environments and natural selection pressures.

Keystone species Species that has a disproportionately greater effect on the ecological processes of an ecosystem, and whose loss would result in significantly greater consequences for other species and biotic interactions.

Organismal (species) diversity Number and relative abundance of all species living in a given area.

Species richness Absolute number of species living in a given area (also called alpha diversity), giving equal weight to all resident species.

Use values Values that are obtained by using a natural resource, such as timber, fuelwood, water, and landscapes. These include direct, indirect, option, and nonuse values.

The word biodiversity is a modern contraction of the term biological diversity. Diversity refers to the range of variation or variety or differences among some set of attributes; biological diversity thus refers to variety within the living world or among and between living organisms.

What is Biodiversity?

The term “biodiversity” was first used in its long version (biological diversity) by Lovejoy (1980) and is most commonly used to describe the number of species. Recognizing that conventional methods of determining, and separating, species were inadequate, others elaborated the definition by including the variety and variability of living organisms.

These reduced and simple definitions, which embrace many different parameters, have been much elaborated and debated in the last three decades (*see* Section on Definition of Biodiversity); on this definition hangs the outcome of important scientific considerations, international agreements, conventions, conservation initiatives, political debates, and socioeconomic issues. Indeed, while the word “biodiversity” has become synonymous with life on earth, the term is commonly used in the fields of politics and environmental technology in addition to various scientific disciplines (Ghikrov, 1996). The US Strategy Conference on Biological Diversity (1981) and the National Forum on Biodiversity (1986) in Washington, DC, were the critical debates in crafting a definition, and it was the proceedings from the latter, edited by E.O. Wilson, that “launched the word ‘biodiversity’ into general use” (Harper and Hawksworth, 1994).

In measuring biodiversity, it is necessary to deconstruct some of the separate elements of which biodiversity is

composed. It has become widespread practice to define biodiversity in terms of genes, species, and ecosystems, for example, “the abundance, variety, and genetic constitution of native animals and plants” (Dodson *et al.*, 1998). Biodiversity also encompasses all five living kingdoms, including fungi. However, biodiversity does not have a universally agreed on definition and it is often redefined on each occasion according to the context and purpose of the author.

Definition of Biodiversity

“Biodiversity” is a relatively new compound word, but biological diversity (when referring to the number of species) is not. Over the last decade its definition has taken a more reductionist turn. Possibly the simplest definition for biodiversity, lacking in specificity or context, is merely the number of species. Yet many have argued that biodiversity does not equate to the number of species in an area. The term for this measure is species richness (Fiedler and Jain, 1992), which is only one component of biodiversity. Biodiversity is also more than species diversity (simply called diversity by some authors), which has been defined as the number of species in an area and their relative abundance (Pielou, 1977).

DeLong (1996) offered a more comprehensive definition:

Biodiversity is an attribute of an area and specifically refers to the variety within and among living organisms, assemblages of living organisms, biotic communities, and biotic processes, whether naturally occurring or modified by humans. Biodiversity can be measured in terms of genetic diversity and the identity and number of different types of species, assemblages of species, biotic communities, and biotic processes, and the amount (e.g., abundance, biomass, cover, rate) and structure

of each. It can be observed and measured at any spatial scale ranging from microsites and habitat patches to the entire biosphere.

This definition allows for modification according to the context in which it is used.

Various authors have proposed specific and detailed elaborations of this definition. [Gaston and Spicer \(1998\)](#) proposed a three-fold definition of “biodiversity” – ecological diversity, genetic diversity, and organismal diversity – while others conjoined the genetic and organismal components, leaving genetic diversity and ecological diversity as the principal components. These latter two elements can be linked to the two major “practical” value systems of direct use/genetics and indirect use/ecological described by [Gaston and Spicer \(1998\)](#). Other workers have emphasized a hierarchical approach or hierarchies of life systems.

In contrast, some argue that biodiversity, according to the definition of biological, does not include the diversity of abiotic components and processes, and that it is inaccurate to identify ecological processes, ecosystems, ecological complexes, and landscapes as components of biodiversity. The term ecological, as used in the sense of ecological system (ecosystem), encompasses both biotic and abiotic components and processes. Therefore, ecological diversity is a more appropriate term for definitions that include the diversity of ecological processes and ecosystems. However, ecological processes, it has been argued, should be included in the definition of biodiversity, the reasoning being that “although ecological processes are as much abiotic as biotic, they are crucial to maintaining biodiversity.” Similarly, a US Bureau of Land Management advisory group included ecological processes in their definition of biodiversity in response to criticism that the [Office of Technology Assessment’s \(1987\)](#) definition did not consider ecosystem form and function. Other writers point out that even though ecological processes are often cited as being crucial to maintaining biodiversity ([Reid and Miller, 1989](#); [Noss and Cooperrider, 1994](#); [Samson and Knopf, 1994](#)), this does not warrant the inclusion of ecological processes into the meaning of biodiversity. For example, [Reid and Miller \(1989\)](#) and [Agarwal \(1992\)](#) distinguished between biodiversity and the processes and ecological diversity that maintain it.

Nevertheless, the jargon word “biodiversity” is, by its very origin, fundamentally indefinable, being a populist word invented for convenience. Its invention has had beneficial effects by fueling research projects, mainly in ecology and systematics, and scientists have been drawn into contributing to the debate by the need to show that biodiversity is useful to humans and necessary for the proper functioning of ecosystems. Conservation (i.e., management) of biodiversity is axiomatic to these two concerns and lies behind the scientific need to define the term within whatever context is appropriate, since no general definition will be suitable when applied across a range of situations.

Biodiversity conservation requires the management of natural resources, and this in turn requires the measurement of these resources. Biodiversity measurement implies the need for some quantitative value that can be ascribed to the various measurements so these values can be compared. Among the first scientists to measure diversity were [Fisher, Corbet, and](#)

[Williams \(1943\)](#), who approximated the frequency distribution of the species represented by $1, 2, 3, 4, \dots$ (and so on) individuals by the logarithmic series $\alpha x, \alpha x^2/2, \alpha x^3/3, \alpha x^4/4, \dots$, where the constant α has been found to be a measure of species diversity. Species diversity is low when the number of species is growing slowly with respect to the increase in number of individuals, and it is high when the number of species is growing quickly.

If the need to quantify biodiversity drives the fundamental meaning of biodiversity, the definition may be limited to that which can be readily measured given current understanding and technologies. Such a definition of biodiversity could change over time as ideas, technology, and resources for measuring diversity change. [DeLong \(1996\)](#) suggested that an operational “clause” should be added to the definition of biodiversity, namely, that “biodiversity is...as measured in terms of...” This approach provides a link to management while distinguishing between what biodiversity is (a state or attribute) and how it is measured. It also allows the operational clause to be adjusted over time without changing the fundamental meaning of the term. A definition of biodiversity should portray the full scope of what the term means, not just what can be measured and managed. In contrast, monitoring or management objectives must be attainable to be effective. Recognizing the distinction between a definition and management objectives should reduce the confusion between the meaning of biodiversity and the objectives for achieving biodiversity goals.

Biodiversity is a broad totality and often embraces elements beyond species diversity or numbers. For example, a major debate in biological sciences over many decades has been that of pattern versus process, especially in systematics and evolutionary studies. Molecular biology and systematics have enabled ecologists to see that inferred history is important in framing appropriate questions, and this understanding has precipitated a real integration of these twin hierarchies – pattern (e.g., diversity) and process (e.g., evolution). Fundamental divisions remain, such as “straight” parsimony (i.e., pattern) versus maximum likelihood (i.e., process) in the phylogenetic interpretation of sequence data.

It is apparent that the term biodiversity still lacks consistent meaning within the field of natural resource management. Michael Soulé found it shocking that “we are still trying to define biological diversity after all of the efforts of the Office of Technology Assessment and E.O. Wilson’s book, *Biodiversity*” ([Hudson, 1991](#)). It is still defined in different ways by different people; some characterize biodiversity as being a widely used term “having no unified definition” and others emphasize or limit the meaning of biodiversity to that of native biodiversity. Some writers have included human alterations of biological communities in the scope of biodiversity ([Bryant and Barber, 1994](#)). [Angermeier \(1994\)](#) argued that “the absence of a ‘native’ criterion within the definition (of biodiversity) severely compromises biodiversity’s utility as a meaningful biological concept,” reasoning that native biodiversity is more valuable than artificial diversity and should be the primary focus of conservation efforts. The conservation of native biodiversity appears to be the theme of biodiversity conservation texts ([Wilson and Peter, 1988](#); [Hunter, 1996](#)). Conversely, others argued that an important component of biodiversity is

maintained by traditional farming techniques. In the context of conserving biodiversity, Reid and Miller (1989) and Bryant and Barber (1994) discussed the importance of genetic diversity within species of cultivated plants. Biodiversity within agricultural plants is important for pest management in agroecosystems and sustainable agriculture.

An accepted fundamental definition of biodiversity is needed for conservation planning, as are effective communication and cooperation within and among different countries, governments, agencies, disciplines, organizations, and private landowners. Cooperation among these entities has been identified as being necessary for the conservation of biodiversity (Babbitt, 1994). Knopf (1992) asserted that the definitions of biodiversity are "as diverse as the biological resource." Definitions of biodiversity range in scope from "the number of different species occurring in some location" to "all of the diversity and variability in nature" and "the variety of life and its processes." A more comprehensive definition is "the variety of living organisms, the genetic differences among them, the communities and ecosystems in which they occur, and the ecological and evolutionary processes that keep them functioning, yet ever changing and adapting" (Noss and Cooperrider, 1994).

This plethora of terms and definitions is one of the major stumbling blocks to reaching agreement in problem solving and decision making. If entities in a planning process view biodiversity in fundamentally different ways, agreement on management objectives and strategies for biodiversity conservation will be impaired. (Swingland, 1999).

The differences between these conceptual perspectives on the meaning of biodiversity, and the associated semantic problems, are not trivial. Management intended to maintain one facet of biodiversity will not necessarily maintain another. For example, a timber extraction program that is designed to conserve biodiversity in the sense of site species richness may well reduce biodiversity measured as genetic variation within the tree species harvested. Clearly, the maintenance of different facets of biodiversity will require different management strategies and resources, and will meet different human needs.

Even if complete knowledge of particular areas could be assumed, and standard definitions of diversity are derived, the ranking of such areas in terms of their importance with respect to biological diversity remains problematic. Much depends on the scale that is being used. Thus, the question of what contribution a given area makes to global biological diversity is very different from the question of what contribution it makes to local, national, or regional biological diversity. This is because, even using a relatively simplified measure, any given area contributes to biological diversity in at least three different ways – through its richness in numbers of species, through the endemism (or geographical uniqueness) of these species (e.g., Mittermeier *et al.*, 1992), and on the basis of degree of threat. The relative importance of these three factors will inevitably change at different geographical scales, and sites of high regional importance may have little significance at a global level. None of these factors includes any explicit assessment of genetic diversity.

Although the word biodiversity has already gained wide currency in the absence of a clear and unique meaning, greater

precision will be required of its users if policy and programs are to be more effectively defined in the future.

Genetic Diversity

Genetic diversity is reliant on the heritable variation within and between populations of organisms. New genetic variation arises in individuals by gene and chromosome mutations, and in organisms with sexual reproduction it can be spread through the population by recombination. It has been estimated that in humans and fruit flies alike, the number of possible combinations of different forms of each gene sequence exceeds the number of atoms in the universe. Other kinds of genetic diversity can be identified at all levels of organization, including the amount of DNA per cell and chromosome structure and number. Selection acts on this pool of genetic variation present within an interbreeding population. Differential survival results in changes of the frequency of genes within this pool, and this is equivalent to population evolution. Genetic variation enables both natural evolutionary change and artificial selective breeding to occur (Thomas, 1992).

Only a small fraction (<1%) of the genetic material of higher organisms is outwardly expressed in the form and function of the organism; the purpose of the remaining DNA and the significance of any variation within it are unclear (Thomas, 1992). Each of the estimated 109 different genes distributed across the world's biota does not make an identical contribution to overall genetic diversity. In particular, those genes that control fundamental biochemical processes are strongly conserved across different taxa and generally show little variation, although such variation that does exist may exert a strong effect on the viability of the organism; the converse is true of other genes. A large amount of molecular variation in the mammalian immune system, for example, is possible on the basis of a small number of inherited genes (Thomas, 1992).

Species Diversity

Historically, species are the fundamental descriptive units of the living world and this is why biodiversity is very commonly, and incorrectly, used as a synonym of species diversity, in particular of "species richness," which is the number of species in a site or habitat. Discussion of global biodiversity is typically presented in terms of global numbers of species in different taxonomic groups. An estimated 1.7 million species have been described to date; estimates for the total number of species existing on earth at present vary from 5 million to nearly 100 million. A conservative working estimate suggests there might be around 12.5 million.

When considering species numbers alone, life on earth appears to consist mostly of insects and microorganisms. The species level is generally regarded as the most natural one at which to consider whole-organism diversity. While species are also the primary focus of evolutionary mechanisms, and the origination and extinction of species are the principal agents in governing biological diversity, species cannot be recognized

and enumerated by systematists with total precision. The concept of what a species is differs considerably among groups of organisms. It is for this reason, among others, that species diversity alone is not a satisfactory basis on which to define biodiversity.

Another reason why a straightforward count of the number of species provides only a partial indication of biological diversity concerns the concept of degree or extent of variation that is implicit within the term biodiversity. By definition, organisms that differ widely from each other in some respect contribute more to overall diversity than those that are very similar. The greater the interspecific differences (e.g., by an isolated position within the taxonomic hierarchy), then the greater contribution to any overall measure of global biological diversity. Thus, the two species of Tuatara (genus *Sphenodon*) in New Zealand, which are the only extant members of the reptile order Rhynchocephalia, are more important in this sense than members of some highly species-rich family of lizards. A site with many different higher taxa present can be said to possess more taxonomic diversity than another site with fewer higher taxa but many more species. Marine habitats frequently have more different phyla but fewer species than terrestrial habitats, that is, higher taxonomic diversity but lower species diversity. By this measure, the Bunaken reef off the north coast of Sulawesi has the highest biodiversity on earth. Current work is attempting to incorporate quantification of the evolutionary uniqueness of species into species-based measures of biodiversity.

The ecological importance of a species can have a direct effect on community structure, and thus on overall biological diversity. For example, a species of tropical rain forest tree that supports an endemic invertebrate fauna of a hundred species makes a greater contribution to the maintenance of global biological diversity than does a European alpine plant that may have no other species wholly dependent on it.

Ecosystem Diversity

While it is possible to define what is in principle meant by genetic and species diversity, it is difficult to make a quantitative assessment of diversity at the ecosystem, habitat, or community level. There is no unique definition or classification of ecosystems at the global level, and it is difficult in practice to assess ecosystem diversity other than on a local or regional basis, and then only largely in terms of vegetation. Ecosystems are further divorced from genes and species in that they explicitly include abiotic components, being partly determined by soil/parent material and climate.

To get around this difficulty, ecosystem diversity is often evaluated through measures of the diversity of the component species. This may involve assessment of the relative abundance of different species as well as consideration of the types of species. The more that species are equally abundant, then the more diverse that area or habitat. Weight is given to the numbers of species in different size classes, at different trophic levels, or in different taxonomic groups. Thus a hypothetical ecosystem consisting only of several plant species would be less diverse than one with the same number of species but that included animal herbivores and predators. Because different

weightings can be given to these different factors when estimating the diversity of particular areas, there is no one authoritative index for measuring ecosystem diversity. This obviously has important implications for the conservation ranking of different areas. In examining beta diversity (i.e., the change in species composition between areas), the only reliable predictor of community similarity is to compare the species composition of the site immediately adjacent.

Biodiversity: Meaning and Measurement

Species Diversity

A.S. Corbet, on analyzing a large collection of butterflies from Malaya, remarked on the decrease in number of new species with an increasing number of individuals. He thought that the resulting distribution could be described by a hyperbola, but R.A. Fisher, to whom Corbet sent his results, suggested that a negative binomial distribution would be much more appropriate (Williams, 1964). As mentioned earlier, Fisher, Corbet, and Williams (1943) approximated the frequency distribution of the species represented by $1, 2, 3, 4, \dots$ (and so on) individuals by the logarithmic series $\alpha x, \alpha x^2/2, \alpha x^3/3, \alpha x^4/4, \dots$, where the constant α is a measure of species diversity. Species diversity is low when the number of species rises slowly with an increase in the number of individuals, and diversity is high when the number of species rises quickly.

Species diversity measurement was thus clearly formulated more than 50 years ago and a particular index was proposed. Fisher *et al.* attempted to find some general “rule” or “law” according to which the numerical abundances of different species were related to each other. In many communities, the number of species with given abundance could be approximated by the log-normal distribution. If species are classified in accordance with their abundance in logarithmically increasing classes – so-called “octaves” (i.e., the first octave contains 1–2 individuals, the second contains 2–4 individuals, the third has 4–8, the fourth has 8–16, and so on) – then the number of species per “octave” shows a truncated normal distribution. If a sample contains a high number of species and individuals, we can usually obtain a log-normal distribution, and it is obviously more tractable than the logarithmic series.

MacArthur (1957) went further by proposing an interesting model that assumed that boundaries between niches in resource–niche hypervolume are set at random, whereas the relative abundances of species are proportional to these sections of hypervolume. This model became widely known as the “broken-stick” or MacArthur’s model. The distribution of abundance prescribed by MacArthur’s model is much “flatter” (i.e., the contrast between given species and the next in the sequence is less) than in the case of a logarithmic series (Ghikrov, 1996).

It has become clear that there is no universal type of distribution of relative abundance that corresponds to all real communities, though such distributions change in the course of succession according to a particular pattern. The dominance of a few of the most abundant species is more pronounced at the early stages of succession, while later the species of

intermediate abundance become more significant (Whittaker, 1972). A comprehensive understanding of the underlying mechanisms that result in a given pattern of species abundance still eludes scientists.

Another line of species diversity studies was connected with the use of special indices proposed to measure diversity without reference to some hypothetical distribution of relative abundance. A great variety of indices were proposed that assess the number of species and the proportions in abundance of different species. Among others, there was the very popular index that is based on Shannon's formula derived from information theory: $H = -\sum p_i \log p_i$ where p_i is the proportion of the total number of individuals that belong to the i th species.

In a seminal work on the measurement of diversity, Whittaker (1972) introduced the concepts of alpha, beta, and gamma diversity. The measurements just described, giving diversity values for single sites, are examples of alpha diversity. The beta and gamma diversity concepts relate to changes in diversity between sites at local (beta) and geographical (gamma) scales. An essential part of these relational concepts is the idea of species turnover – the degree to which species replace other species at different sites. For use in assessing the relative value of multiple sites for the conservation of biodiversity, the idea of species turnover is translated into the principle of complementarity (see Section on Loss of Biodiversity and Causes), which can be implemented in combination with a taxonomic diversity index.

Taxonomic Diversity

Biodiversity measurements that measure genetic difference directly, or indirectly through use of the taxonomic (cladistic) hierarchy (Williams *et al.*, 1991), are currently being used. The indirect taxonomic approach is more practical because we already have a “rule of thumb” taxonomic hierarchy (which is being steadily improved through the application of cladistic analysis, notably to molecular data), whereas reliable estimates of overall genetic differences between taxa are virtually nonexistent (abridged from Vane-Wright, 1992).

Based on the shared and unshared nodes between taxa (equivalent to position in the taxonomic hierarchy), a number of taxonomic diversity indices have now been developed. Of these, the most distinct are root weight, higher taxon richness, and taxonomic dispersion. The first places highest individual value on taxa that separate closest to the root of the cladogram and comprise only one or relatively few species; in effect this gives high weighting to relict groups (Vane-Wright, 1996). Higher taxon richness favors taxa according to their rank and number of included species. Dispersion, the most complex of the measures proposed so far (Williams *et al.*, 1991), endeavors to select an even spread of taxa across the hierarchy, sampling a mixture of high, low, and intermediate ranking groups.

For a given group these measures, together with simple species richness if desired, can be used to compare the biotic diversity of any number of sites. The measures can also be expressed as percentages. Thus a site with viable populations of all species in a group would have a diversity score of 100%, whereas a site without any species of the group in question

would score zero. In reality, of course, most sites have only a selection of species, and so receive various intermediate scores. Such assessments allow us to compare all sites with each other, and rank them individually from highest to lowest diversity (Vane-Wright, 1996). However, if we then take some conservation action (such as conserving a particular site), the same measures are unlikely to be directly comparable for making a second decision (such as choosing a second conservation site). This is because, in most real situations at least, there will be considerable overlap in the presence of species at particular sites.

Community Diversity

Early ecologists did not confine themselves to measuring species diversity. They also tried to understand the relationship of diversity with other features of the community (e.g., Williams, 1964; Whittaker, 1972). The dependence of species diversity on the structural complexity of the environment was demonstrated (MacArthur and MacArthur, 1961), as was the role of predation (Addicott, 1974) and periodical disturbance (Sousa, 1979) in determining a given level of diversity. The relationship between the species diversity and standing crop of a community was also shown (Ghilarov and Timonin, 1972).

Margalef (1957) was the first to use the Shannon index (though expressed in a different form). He proposed to evaluate the level of community organization in terms of information theory. Margalef stimulated many ecologists to quantitatively measure the species diversity of different communities or of the same community in different stages of its development. At that time, there was a widespread belief that with a single numerical value, an assessment could be made of some very significant feature of community structure. Many ecologists believed that in measuring species diversity at the community level they were using an approach that was fundamental to an understanding of diversity (Ghikrov, 1996).

Ecologists have measured diversity either by estimating species richness (number of species) in an area, or by using one or more indices combining species richness and relative abundance within an area. Some attempts have also been made to measure change in species richness (species turnover) between areas. These solutions to the problem of measuring biodiversity are limited because species richness takes no account of the differences between species in relation to their place in the natural hierarchy. Moreover, relative abundance is not a fixed property of a species, for it varies widely from time to time and place to place. In many environments most taxa are virtually or even completely unknown.

Conservation biologists, or applied ecologists, have called for a measurement of diversity that is more clearly related to overall genetic difference. An example concerns the problem of differential extinction. In *World Conservation Strategy* (IUCN/UNEP/WWF, 1980), it is noted that “the size of the potential genetic loss is related to the taxonomic hierarchy because...different positions in this hierarchy reflect greater or lesser degrees of genetic difference.... The current taxonomic hierarchy provides the only convenient rule of thumb for determining the relative size of a potential loss of genetic material.”

Synthesis

A model incorporating island biogeographic theory, species abundance, and speciation, and that produces a fundamental biodiversity number (θ) that is closely associated with species richness and abundance in an equilibrium metapopulation, has been proposed in [Hubbell's unified theory \(1997\)](#). This model assumes zero-sum community dynamics or a saturated, totally stochastic local community, which limits its application, but it advances the study of species richness and relative abundance if others can extend its usefulness to the nonequilibrium systems that characterize the real world.

Biodiversity: Changes in Time and Space

Changes Over Time

The fossil record is very incomplete, which emphasizes the marked variation between higher taxa and between species in different ecosystems in the extent to which individuals are susceptible to preservation and subsequent discovery. Chance discovery has played a large part in compiling the known fossil record, and interpretation by paleontologists of the available material is beset by differences of opinion. Thus, the record is relatively good for shallow-water, hard-bodied marine invertebrates, but poor for most other groups, such as plants in moist tropical uplands.

Two relevant points appear to be well substantiated. First, taxonomic diversity, as measured by the number of recognized phyla of organisms, was greater in Cambrian times than in any later period. Second, it appears that species diversity and the number of families have undergone a net increase between the Cambrian and Pleistocene epochs, although interrupted by isolated phases of mass extinction (few of which are reflected in the fossil record of plants).

Changes in Space

Species diversity in natural habitats is high in warm areas and decreases with increasing latitude and altitude; additionally, terrestrial diversity is usually higher in areas of high rainfall and lower in drier areas. The richest areas are tropical moist forest and, if current estimates of the number of microfaunal species (mainly insects) of tropical moist forests are credible, then these areas, which cover perhaps 7% of the world's surface area, may well contain over 90% of all species. If the diversity of larger organisms only is considered, then coral reefs such as Bunaken (see earlier) and, for plants at least, areas with a Mediterranean climate in South Africa and Western Australia may be as diverse. Gross genetic diversity and ecosystem diversity will tend to be positively correlated with species diversity.

What are not fully understood are the reasons for the large-scale geographic variation in species diversity, and in particular for the very high species diversity of tropical moist forests. The origin of diversity through the evolution of species and the maintenance of this diversity both need more study before they are better understood. This will require consideration of the present and historic (in a geological or evolutionary sense)

conditions prevailing in particular areas, principally climatic but also edaphic and topographic. Climatically benign conditions (warmth, moisture, and relative seasonality) over long periods of time appear to be particularly important.

Climax ecosystems will be more diverse than areas at earlier successional stages, but an area with a mosaic of systems at different successional stages will probably be more diverse than the same area at climax provided that each system occupies a sufficiently large area of its own. In many instances, human activities artificially maintain ecosystems at lower successional stages. In areas that have been under human influence for extended periods, notably in temperate regions, maintenance of existing levels of diversity may involve the maintenance of at least partially man-made landscapes and ecosystems, mixed with adequately sized areas of natural climax ecosystems.

Loss of Biodiversity and Causes

Species extinction is a natural process that occurs without the intervention of humans since, over geological time, all species have a finite span of existence. Extinctions caused directly or indirectly by humans are occurring at a rate that far exceeds any reasonable estimates of background extinction rates, and to the extent that these extinctions are correlated with habitat perturbation, they must be increasing.

Quantifying rates of species extinction is difficult and predicting future rates with precision is impossible. The documentation of definite species extinctions is only realistic under a relatively limited set of circumstances, for example, where a described species is readily visible and has a well-defined range that can be surveyed repeatedly. Unsurprisingly, most documented extinctions are of species that are easy to record and that inhabit sites that can be relatively easily inventoried. The large number of extinct species on oceanic islands is not solely an artifact of recording, because island species are generally more prone to extinction as a result of human actions.

Most global extinction rates are derived from extrapolations of measured and predicted rates of habitat loss, and estimates of species richness in different habitats. These two estimates are interpreted in the light of a principle derived from island biogeography, which states that the size of an area and of its species complement tend to have a predictable relationship. Fewer species are able to persist in a number of small habitat fragments than in the original unfragmented habitat, and this can result in the extinction of species ([MacArthur and Wilson, 1967](#)). These estimates involve large degrees of uncertainty, and predictions of current and future extinction rates should be interpreted with considerable caution. The pursuit of increased accuracy in the estimation of global extinction rates is not crucial. It is more important to recognize in general terms the extent to which populations and species that are not monitored are likely to be subject to fragmentation and extinction ([Temple, 1986](#)).

Loss of biodiversity in the form of domesticated animal breeds and plant varieties is of little significance in terms of overall global diversity, but genetic erosion in these populations is of particular human concern in so far as it has

implications for food supply and the sustainability of locally adapted agricultural practices. For domesticated populations, the loss of wild relatives of crop or timber plants is of special concern for the same reason. These genetic resources may not only underlie the productivity of local agricultural systems but may also, when incorporated into breeding programs, provide the foundation of traits (disease resistance, nutritional value, hardiness, etc.) that are of global importance in intensive systems and that will assume even greater importance in the context of future climate change. Erosion of diversity in crop gene pools is difficult to demonstrate quantitatively, but can be indirectly assessed in terms of the increasing proportion of world cropland planted to high-yielding, but genetically uniform, varieties. Genetic modification of organisms, varieties, or cultivars for food production, pharmaceuticals, and other products, which has caused concern in some countries but not others, may also contribute to the loss of biodiversity.

Humans exterminate species either directly by hunting, collection, and persecution or indirectly through habitat destruction and modification. Overhunting is perhaps the most obvious direct cause of extinction in animals, but it is undoubtedly far less important than the indirect causes of habitat modification in terms of overall loss of biodiversity. Hunting selectively affects the targeted species, as well as plant and animal species whose populations are subsequently affected either negatively or positively, and so it has important implications for the management of natural resources. Genetic diversity in a hunted population is liable to decrease as a result of the same factors. The genetic diversity represented by populations of crop plants or livestock is also likely to decline as a result of mass production, for the desired economics of scale demand high levels of uniformity.

Sustained human activity will affect the relative abundance of species and in extreme cases may lead to extinction. This may result from the habitat being made unsuitable for the species (e.g., clear-felling of forests or severe pollution of rivers) or through the habitat becoming fragmented (discussed earlier). Fragmentation divides previously contiguous populations of species into small subpopulations. If these are sufficiently small, then chance processes lead to higher probabilities of extinction within a relatively short time. Major changes in natural environments are likely to occur within the next century as a result of changes in global climate and weather patterns. These will cause greatly elevated extinction rates.

Maintaining Biodiversity

In Situ Conservation

The maintenance of biological diversity is the sustainable management of viable populations of species or populations *in situ* or *ex situ*. The maintenance of a significant proportion of the world's biological diversity only appears feasible by maintaining organisms in their wild state and within their existing range. This allows for continuing adaptation of wild populations by natural evolutionary processes and, in principle, for current utilization practices to continue. For such maintenance to succeed, it almost invariably requires

enhanced management through the integrated, community-based conservation of protected areas.

Over the last 30 years, conservation biologists have struggled with the concept of the maintenance of biodiversity in highly diverse environments like rain forests. Analytical techniques (neural-net models) that allow us to reconstruct past distributions of forest types present an opportunity to predict past contractions and expansions of forest forms, and the likelihood of refugia surviving climate change. Such extrapolations must be treated with caution, as pollen samples from Brazil (for example) disproved modeling predictions that savanna grasslands should have been extant, when in fact tropical and temperate forests were present. Various authors also opposed the Pleistocene refugia hypothesis (Haffer, 1969) for the Amazon region because some evidence demonstrated the lack of rain forest fragmentation during that era. In the biogeographical zones of the Australian wet tropics, there is a strong correlation between diversity patterns and reputed rain forest refugia in both species and genetic diversity. However, this appears to have been caused by differential extinction rates in differently sized refugia rather than by allopatric speciation in the Pleistocene. Others have emphasized that a greater concentration on the Pliocene or before would be useful, since most tropical species radiations occurred before the Pleistocene.

The local-determination hypothesis of species diversity (Rosenzweig, 1995), which predicts similar species diversity in similar habitats, has also been challenged. In sister taxa of plants, the net diversification was significantly higher in Asia than in North America for genera shared between the two continents. Greater insights into the effects of current ecology on the local diversity of an area may be assisted by considering the relative ages of clades, which could establish species proliferation rates between regions, thus advancing the local versus regional diversity debate (Ricklefs and Schluter, 1993). They also tested the taxon cycle theory (Wilson, 1961) using phylogenies of bird species and showed that older species' lineages had more restricted ranges, smaller habitat breadth, and more fragmented distributions, and were closer to extinction than younger species.

In efforts to conserve biodiversity, preserving genetic dissimilarity is often a higher priority than maintaining genes of considerable similarity. Recent work shows that genetic divergence in mammals increases from the headwaters to the mouth as a river gets broader and thus becomes a greater barrier to populations on opposite banks; this effect promotes species diversity through allopatric speciation. Headwater species are basal in the phylogeny, and shared haplotypes occur only at the headwaters; this research is a contribution to Wallace's riverine diversification hypothesis in the Amazon basin.

A central question in the design of effective conservation programs is what geographical regions to protect in order to maintain the most biological diversity. The term biodiversity hotspot was coined by Myers (Myers, 1990) and most commonly refers to regions of high species richness. GAP analysis is used to identify gaps in existing protected area networks (Scott *et al.*, 1993); it uses algorithms to select the minimum set of grid cells that encompass the unprotected species. Rarity and endemism have been used to define hotspots in bird conservation (Balmford and Long, 1994), and species richness and endemism have been used to rank countries (McNeely *et al.*, 1990).

Hotspots are also defined as those areas with the greatest number of threatened species.

In setting conservation priorities, assumptions are made that indicator groups (e.g., macroorganisms such as birds, mammals, and plants) are good predictors of biological diversity in general. Another question that arises is how best to analyze biodiversity information to generate accurate and useful analyses that will inform conservation decisions. On a large scale, some concordance is found between bird diversity across continents with insect diversity (Pearson and Cassola, 1992), and in endemism patterns across taxa (Lawton, 1994); but at a finer spatial scale this correlation begins to break down. Richness in genera and families are good predictors of species richness at a finer level (Balmford *et al.* (1996a) and Balmford *et al.* (1996b)). However, species richness is not a good measure with which to identify hotspots for conservation because it overlooks rare species, although as the sample area for hotspots is increased, more rare species are included as a simple function of arithmetic progression. Rarity and endemism are efficient indices for selecting the most parsimonious number of sites, but compared to complementarity measures they are less useful in defining conservation priorities.

A good conservation measure is complementarity, where the species complement of a reserve or area is identified and then further sites are found that add the greatest number of new species; this is akin to the portfolio approach (Swingland, 1997). Another method using integer linear programming to choose the optimal set of sites (maximal-covering-location; Church *et al.*, 1996) is limited to small datasets and does not achieve the greatest conservation gain for the fewest additional sites. Clearly, combining an ecosystem portfolio approach with a richness or endemism assessment would be effective, but differing approaches are needed according to the conservation goal and data availability.

Ex Situ Conservation

Viable populations of many organisms can be maintained in cultivation or in captivity. Plants may also be maintained in seed banks and germplasm collections; similar techniques are under development for animals (storage of embryos, eggs, and sperm, i.e., “frozen zoos”) but are more problematic. *Ex situ* conservation is extremely costly in the case of most animals, and while it would in principle be possible to conserve a very large proportion of higher plants *ex situ*, this would be feasible for only a small percentage of the world’s organisms. Furthermore, it often involves a loss of genetic diversity through founder effects and the high probability of inbreeding (Milner-Gulland and Mace, 1998).

Contextual Variations of the Definition

Derivation of “Biodiversity”

The definition of biodiversity put forth by the Office of Technology Assessment (1987) appears to be the most widely cited basis for other published definitions (Scott *et al.*, 1995). However, the OTA did not explain why they defined the term as they did, nor did they cite any supportive documentation. One problem with relying solely on authoritative sources for

definitions of biodiversity is that different authorities have defined the term in fundamentally different ways.

“Bio” is derived from the Greek word *bios*, meaning life. “Biological” and “biotic” are terms that refer to life, living organisms, assemblages of living organisms, and the activities and interactions of living organisms. The scope of the term “biological” can be further understood in the context of components and processes that are considered biological. Defining biodiversity (i.e., diversity) is more difficult because it continues to be defined in several fundamentally different ways. In definitions of biodiversity, diversity has been characterized as (1) the number of different types of items, (2) the number of different types of items and their relative abundance, and (3) variety. Characterization of diversity in discussions of biodiversity has also included the structural complexity of landscapes (Huston, 1994).

Classifying Biodiversity

The classification of biodiversity can be divided into those authors who consider biodiversity to be a state and those who believe that it is a measure of the state.

Most authors have defined biodiversity as a state or attribute, for example, “biodiversity is the variety of...” or “variety and variability of...” (Noss and Cooperrider, 1994). Standard dictionaries have classified diversity as a state, condition, or quality (Soukhanov *et al.*, 1988).

Other definitions of biodiversity limited the scope of the attribute to explicit, quantifiable dimensions or measures, for example, “biodiversity is the number of...” or “the number and relative abundance of...” (Office of Technology Assessment, 1987). This emphasis on quantitative, operational definitions of biodiversity, and criticisms of nonquantitative definitions (Angermeier, 1994; Hunter, 1996) may signal a potential shift in the classification of the term from an attribute to a measure of an attribute. In the ecological and natural resource management literature, Pielou (1977) and others have treated diversity as a one- or two-dimensional attribute of a community (e.g., diversity is “the number of” or “the number and relative abundance of”). More recently, it has been defined as a measure or index of those attributes; for example, diversity is a “measure of...” (Noss and Cooperrider, 1994). Operational definitions of biodiversity (Angermeier, 1994) provide impetus to define biodiversity in quantitative terms as Hunter (1996) recommended.

Attributes of Biodiversity

Another way of delineating the meaning of a term is to list its characteristics, properties, qualities, and parts. Noss (1990) recognized three main attributes of biodiversity: composition, structure, and function.

Composition addresses the identity and richness of biotic components, and the relative amount (e.g., abundance, cover, biomass) of each (Noss, 1990). Biotic components of ecosystems include genes, organisms, family units, populations, age classes, species and other taxonomic categories, trophic levels of animals (e.g., herbivores, predators), animal guilds and assemblages, plant communities, and interacting

assemblages of plants, animals, and microorganisms (i.e., biotic communities).

Structural attributes of biodiversity refer to the various vertical and horizontal components of a community or landscape (Noss, 1990) and the organizational levels of plant and animal populations and assemblages (Gaston and Spicer, 1998; Hunter, 1996). Considering only biotic, vegetative components of a landscape, horizontal structure consists of the size, shape, and spatial arrangement and juxtaposition of different plant communities; vertical structure consists of the foliage density and height of different vegetation layers (Noss, 1990). Structure can also refer to population, age and trophic structure, and other levels of community organization (Hunter, 1996).

The inclusion of structure in the meaning of biodiversity provides linkages with other concepts, such as habitat diversity and the plant community concept, for both of which vegetation structure is an important differentiating attribute. Structure may have been left out of most definitions of biodiversity because the concept of biodiversity evolved from the concept of ecological diversity, which primarily focused on species diversity (Fisher *et al.*, 1943). Interestingly, 20 years ago it was asserted that measurements of diversity should not preclude structural diversity even though the term is most often used in reference to species diversity. Diversity can also be used in reference to niche width and the structural complexity of habitats.

Biotic functions represent the third component of biodiversity, and these include processes such as herbivory, predation, parasitism, mortality, production, vegetative succession, nutrient cycling and energy flow through biotic communities, colonization and extinction, genetic drift, and mutation (Noss, 1990). Biotic processes can be addressed in terms of the identity and number of different types of processes, as well as the rate (e.g., predation rate) at which each process operates.

Diversity of biotic components and processes can be observed at many biogeographic scales, from microsites and larger-scale landscape elements (e.g., vegetation types, habitat types, range sites) to regional landscapes, biomes, continents, hemispheres, and the entire biosphere (Noss, 1990; Huston, 1994; Hunter, 1996). Although these are scales at which biodiversity can be observed, they are not necessarily scales of biodiversity because most include abiotic (e.g., geological) features. Biodiversity can also be observed at several organism-based scales, including individual organisms, populations, species, and assemblages (e.g., guilds and plant communities), which themselves can be observed at various biogeographical scales.

Biological Resource Asset and Management Objectives

The contextual variations in the definition of biodiversity depend on what use is being made of the biological resource asset (or bioasset), and thus the asset management objective. Biological resource values consist of direct use, indirect use, and option and nonuse values. For the purposes of assessing potential use, they can be further classified as follows:

- Direct use values of major extractive products. Principally, this would include forestry for timber and commercial

fisheries in the case of terrestrial and marine systems. Extraction of these products often involves substantial investment in capital equipment by large nonlocal firms, and the products are transported and sold in well-developed markets far from their original source.

- Direct use values of “minor” extractive products. These are naturally or seminaturally occurring products that require labor-intensive gathering or harvesting activities, often carried out by local people. Examples include rattan, fuelwood, seaweed, wild foods, artisanal fisheries, aquarium fish, and medicinal herbs. These may be collected for sale, barter, or home consumption.
- Direct use values that require the extraction of only a small amount of biological material for *ex situ* research or storage. This includes extraction of material for biological inventories, germplasm banks, and industrial research. Extraction is often accomplished during short or long expeditions that traverse large areas to collect representative samples of biological material.
- Direct use values that are nonextractive, but often require considerable on-site interaction of the user with the resource. This includes ecotourism, recreation, on-site research, and other major “nonconsumptive” activities occurring principally in protected areas. These activities are characterized by the need to provide food, lodging, and transport to the participants.
- Indirect use values that accrue on site. The primary feature of these values is that they support or protect the basic functioning of the protected area. Examples include nutrient cycling, stabilization of soils in erosion-prone areas, coastal zone stabilization, and biological support to local ecosystems. As a result of their nature, the value of these on-site functions is likely to be a component of all the other direct and nonuse values generated by the area.
- Indirect use values that accrue off site. The value of these functions – such as watershed protection, natural ecosystems protected as national parks in generating income from wildlife tourism, protection of fisheries’ nurseries and subsistence fisheries, and climate regulation – may be very large or very small depending on their relative importance to the support or protection of off-site economic activity.
- Option values. Because option values may be associated with each and every use value, they are considered only where they may be of potential significance in conjunction with the particular type of product or service.
- Nonuse values. By their very nature these values occur at a distance from the resource and require no extraction or physical interaction with the resource, for example, stewardship, ethics, cultural belief, and esthetics.

These foregoing values are only indirectly related to biological diversity. That is, a certain level of species richness is required for these functions but there is not necessarily a direct correlation between the value of the ecosystem and its diversity. Thus, mangrove ecosystems are generally of far lower diversity than adjacent lowland terrestrial forests, but in resource terms they are likely to be of comparable value. The savannas of eastern and southern Africa, which are of great importance in generating revenues from tourism, are less diverse than the

moist forests in these countries, which have far less potential for tourism.

Cave Canem or the Precautionary Principle

At present, humans actively exploit a relatively small proportion of the world's biological diversity. Many other potential, yet undiscovered, optional and nonuse values of biodiversity exist. These factors support a precautionary approach to maintaining biological diversity. In this case, the precautionary principle argues that actions should be taken to prevent further loss of biodiversity and potentially irreversible consequences before all biological uncertainties are resolved. Yet in conserving biodiversity, there must come a point at which the projected costs required to protect and maintain it will outweigh any probable benefits.

If species are to be viewed as a resource, and their maintenance is to be cost-effective, conservation should concentrate on systems and areas rich in species, and on those species known to be useful, or regarded as having a high probability of being useful. Thus biodiversity and its conservation would be defined purely along operational or cost-benefit lines. This bioasset perspective on biodiversity would therefore rest on economic arguments more than biological ones.

Biodiversity has been identified as important for ecosystem health, medicinal values, agricultural purposes, and esthetic and recreational values (Noss and Cooperrider, 1994). Noss (1990) characterized an operational definition as one that is responsive to real-life management and regulatory questions, adding that such a definition is unlikely to be found for biodiversity. Angermeier (1994) referred to an operational definition in a similar way, and Hunter (1996) suggested that a quantitative definition is needed for monitoring biodiversity and developing management plans. However, some writers assert that the confounding of definition and application is partly to blame for the confusion over how biodiversity concepts can be practically implemented.

Implications of Variations in the Definition

The need for an unequivocal and precise meaning of biodiversity that is scientifically sensible and universally applicable is imperative to help guide the design of policy and programs for the future, as well as to make critical decisions in the present. Currently, such a definition does not exist. As a concept, biodiversity is both ubiquitous and useful, particular and confusing; and for this reason it is constantly redefined on nearly every occasion.

One of the many reasons for this state of affairs is that the definition of biodiversity affects objectives in national and regional research and conservation management, and in international funding priorities. One could easily promote a timber extraction or nontimber forest product program that conserves species richness (i.e., numbers of species) at the expense of genetic diversity. Indeed, a current research program to stimulate or increase the range of tropical tree species not currently in trade, as a way to take the pressure off overexploited species, may be misguided. It may lead to increased

genetic as well as species impoverishment when foresters expand the number of species they take and select only the best and most mature specimens, thus removing the most productive and healthiest genetic stock.

Apart from the principal definitions of biodiversity discussed earlier, such as the highest number of species (i.e., species richness) and the highest level of species endemism (Myers, 1990) or taxal endemism (called critical faunas analysis), interpretations of pure or applied definitions are becoming more common within the vocabulary of conservation and biodiversity utilization when determining biodiversity management priorities. Some examples are national biodiversity programs that maintain "biodiversity portfolios"; biodiversity defined as flagship or keystone species diversity; viability modeling (population viability analysis) defining the species' populations to be prioritized; population analysis defining sustainability and thus defining a species' status; projects that focus on the feasibility of integrating the targeted species, assemblages, or ecosystems with the needs of local human populations and sustainable use; and (lastly) political exigency (Swingland, 1997). Although the conservation policy of a country may be driven by more pressing needs – family planning, education, politics, internal conflict, financial planning and investment, individual vested interests – current policy and decisions are also being made on the foregoing biodiversity bases rather than along strict academic lines.

Endemism and species richness are useful starting points in defining priorities on the global level, but without information on the possibility of extinction using viability modeling or population analysis, the urgency of a given conservation action cannot be assessed. Moreover, with the increasing emphasis on the integration of local people into conservation programs to minimize long-term costs and to provide a more stable basis for the people and their natural environment, the potential for community-based conservation, coupled with sustainable use, cannot be ignored. Since national or external funding will generally provide essential support for most projects, the ecological importance of an area relative to others using an ecosystem diversity (or portfolio) approach will be a major selection criterion. The presence of a flagship or keystone species will also be significant in raising such funds. Clearly political exigencies or pure chance can enter the situation, and scientists have yet to articulate whether genetic diversity should be used as the key measure. In the absence of realistic methods of quantifying these biodiversity characteristics, they must remain imponderable objectives for the moment.

The differing approaches being advocated for biodiversity conservation are not just guided by the available methodologies but are also symptomatic of the underlying philosophies. The evolution-based approach is predominantly the preserve of biologists, and it is concerned with the maintenance of diversity as an unqualified objective unaffected by economics. The need for conservation and the uses of biodiversity – the resource-based argument – are what are used to "sell" the proposition to decision makers and policy-makers. Where these factors come together, the ideal of ecological sustainability and the conservation methods of achieving it will be possible. Because so much is now formally invested in using the word "biodiversity", its definition will continue to

play a crucial role in both conservation planning and public policy.

Glossary

Density dependence The condition that environmental factors influence population growth rate in relation to population size. Density dependence usually is seen as a linear, inverse relationship between population growth rate and population density (i.e., population growth decreases as density increases) and may occur if individuals compete or predators are more effective as a prey population increases.

Density independence The absence of environmental factors that influence population growth as a function of density. This may occur if mortality removes a fixed percentage of a population, independent of population size.

Logistic growth Regulated population growth that follows the logistic equation $dN/dt = rN(1 - N/K)$.

Populations growing according to this equation increase

rapidly at low densities and the growth rate decreases as they approach carrying capacity (K).

Population A group of individuals of a particular species that live in a region. A population is usually a subset of the entire species.

Population regulation The constraint of positive population growth. The study of population regulation deals with the factors that cause this constraint, such as competition for food or predation.

Population stability The tendency for populations to return to a previous size after a disturbance, such as reductions due to hunting or disease or increases due to immigration. Stable populations may be locally stable (return after small disturbances) or globally stable (return after severe or catastrophic disturbances).

Introduction

Populations, or groups of individuals within a species, change over time. There is a general agreement among ecologists that population growth is bounded by biotic and abiotic environmental factors that result in approximate, maximum numbers of organisms that can be supported in different habitats. A population's carrying capacity is difficult to measure and likely varies over time and through space. The concept of carrying capacity has played an important role in the fields of basic ecological research, wildlife management, and conservation biology.

The concept of carrying capacity also involves determining how many people Earth can support. Dialogs about human carrying capacity are often quite contentious and illustrate the difficulty surrounding the concept of carrying capacity.

The concept of carrying capacity is alive and well, although some have argued that it should be abandoned altogether. On the surface, the concept is easy to understand and intuitive and, therefore, is likely to stay with us for some time. However, recent developments in our understanding of the dynamics of population change over time have, greatly modified what is considered an area's carrying capacity. Therefore, we need to recognize both the strengths and the weaknesses of the concept of carrying capacity.

Origin of the Concept of Carrying Capacity

Recognition of carrying capacity probably occurred long before written history began. It is likely that the earliest agriculturists, perhaps 10,000 years ago, were keenly aware of the number of mouths that an area could sustainably feed and that increasing numbers of people required increases in food

production (i.e., area of land in cultivation). Long before agriculture, hunter-gatherer groups likely were aware of the sustainable number of members that regions could support, although it may be argued that high mortality rates inhibited these early populations from pushing the limits of sustainability. During difficult times populations reached or exceeded what we might think of as a carrying capacity, possibly imposing nomadic lifestyles in which groups had to intermittently move after local resources were depleted. Speculating on past population dynamics hints at the trouble with the concept of carrying capacity: It must represent a dynamic value that changes over time and is highly dependent on many interacting factors, such as environmental variability and, for early humans, what hungry animals awaited their forays. This makes the concept difficult to use.

Charles Darwin (1859), on page 116 of his book *Origin of Species*, quoted in his third chapter on the struggle of existence from Malthus' 1798 "An Essay on the Principle of Population as it Affects the Future Improvement of Society:"

A struggle for existence inevitably follows from the high rate at which all organic beings tend to increase. Every being, which during its natural lifetime produces several eggs or seeds, must suffer destruction during some period of its life, and during some season or occasional year, otherwise, on the principle of geometrical increase, its numbers would quickly become so inordinately great that no country could support the product. Hence, as more individuals are produced than can possibly survive, there must in every case be a struggle for existence, either one individual with another of the same species, or with the individuals of distinct species, or with the physical conditions of life. It is the doctrine of Malthus applied with manifold force to the whole animal and vegetable kingdoms; for in this case there can be no artificial increase of food, and no prudential restraint from marriage. Although

some species may be now increasing, more or less rapidly, in numbers, all cannot do so, for the world would not hold them.

Malthus' clear recognition of the importance of limitations of growth in populations helped Darwin to lay the foundation for his theory of natural selection, which is built on the premise that populations are regulated primarily by competition which leads to differential reproduction.

The earliest concise description of carrying capacity is derived from Pierre Francois Verhulst, a Belgian who lived in the mid-nineteenth century. Verhulst, perplexed on account that the human population appeared to be increasing exponentially, derived a mathematical formula which he called the "logistic" equation that would account for a slowing in the population growth rate as a function of population size. The same relationship was rediscovered by Pearl and Reed (1920), who used the logistic equation to predict the population of the US based on census data collected from 1790 to 1910 (apparently neglecting the fact that the area of the US increased more than threefold during this time). The resulting application of the logistic equation to US census data led Pearl and Reed to greatly underestimate the US population, predicting it would level off at about 197 million in the year 2050 (Figure 1).

The failure of Pearl and Reed to accurately predict the population of the US, currently at about 275 million, reveals at least one important aspect of mathematical models. It indicates that, for the US human population, some aspect of the logistic equation must be wrong. Two candidate problems include violations of the assumptions that the area of the US remained constant and that the US population lacked immigration. These differences between data and model predictions

can help us to better understand the problem at hand. In this example, the violations of model assumptions leads us to re-evaluate the factors that influence population growth and ultimately regulate it. The prediction from the model also clearly did not hold for a variety of socioeconomic and human health reasons and may have been wrong for statistical reasons. Using the logistic equation (based on the filled data points in Figure 1) to predict population size well into the future, without providing confidence limits, is clearly tenuous at best. These problems have led us to be more careful in our predictions of how populations change over time and whether a carrying capacity can be predicted from such data or even exists.

Definitions of Carrying Capacity

Carrying capacity is the maximum population that a given area can sustain. The measures commonly used include the number of individuals or the total biomass of a population, which are each highly dependent on differences in physiology and age structure among species and across large taxonomic groups. The use of the term carrying capacity has changed over time, but most models suggest that population growth is rapid when density is low and decreases as populations increase towards some maximum. In addition, any definition of this concept improves as we narrow the time and area for the population that we are studying. Population descriptions, therefore, are often depicted as densities, accounting for the number of individuals per unit area. Population density usually varies over time and from place to place. In practice, we generally use population size or density to describe carrying

Figure 1 Data on the growth of the US population from 1790 to 1910 (●) and from 1920 to 1990 (○). The dotted line represents Pearl and Reed's fit of the logistic equation, yielding a carrying capacity (K) of about 197 million people, estimated to be reached in about the year 2050. The population in the year 2000 is about 275 million (not shown).

capacity, which is determined either by resource availability or by the influence of enemies (predators and/or pathogens).

Various definitions of carrying capacity arose in the twentieth century, ranging from the suggestion that carrying capacity is that level below which predators have no effect on a population to the population size which can be maximally supported in a given region (previously referred to as the "saturation level"). There also has been a distinction made between "ecological carrying capacity," which refers to the limitation of a population due to resources, and a management oriented, maximum sustainable yield for a population, referred to as an "economic carrying capacity," which is usually lower than ecological carrying capacity. These definitions clearly lead to difficulty for wildlife managers who have been preoccupied with attempting to determine whether populations are either too high or too low. These debates continue, as exemplified by range management decisions in Yellowstone National Park and issues regarding the increasing frequency of reintroduction programs of top predators.

Carrying capacity may best be expressed mathematically. One of the simplest forms of population change over time can be represented as the differential equation $dN/dt = rN$, where dN/dt represents the instantaneous change in a population over a short time period, r is the intrinsic growth rate of the population, and N is the size of the population. This yields, what is often referred to as a "J" curve, or exponential growth (Figure 2). In discrete time this relationship is referred to as geometric growth.

In 1838, Verhulst modified the exponential growth equation and derived the logistic equation that depicted population growth rate as being inversely related to population size. To slow population growth he added an additional term yielding $dN/dt = rN(1 - N/K)$, where K is the population carrying capacity. The term $1 - N/K$ slows growth rate linearly toward zero as the population (N) approaches the carrying capacity (K). This results in a sigmoidal S-shaped curve for an increasing population over time (Figure 2). If the population exceeds K ($N > K$), then $1 - N/K$ is negative, causing growth rate dN/dt to be negative and the population to decline monotonically toward K .

Figure 2 Comparison of unregulated exponential growth (solid line) with regulated logistic growth (dotted line).

An important attribute to bear in mind is that the logistic equation is deterministic, meaning that if we use the equation to predict population size, at the end of a fixed amount of time we will derive the same population each time we start the population over. This assumption is usually violated in field conditions in which random effects, such as accidental deaths, failure to find mates, or fluctuations in environmental conditions, are common. Therefore, it has been argued that we should not expect real populations to behave according to the logistic equation.

This simple equation has been challenged repeatedly by critics without apparent damage. This resilience of a theory is rather rare in science, which is a discipline that prides itself on being able to quickly dispel hypotheses (or equations), given even a small amount of contradictory data. However, the intuitive nature of the idea that populations are regulated by factors such as food supply helps the logistic equation to remain a staple in ecological texts and classrooms. The reason why this equation and carrying capacity (K) endure is that the equation's shortcomings help us better understand the dynamics of real populations, ensuring its utility for many years to come.

The discrete, or difference, form of the logistic equation yields a different prediction of population behavior compared to the previously described continuous version. In particular, the discrete form was the equation used by Robert May to first describe how a simple, deterministic equation could produce chaotic population dynamics, a pattern that emerges when intrinsic growth is relatively high. This chaotic behavior appears to mimic realistic changes in populations over time. Several long-term data records conform to chaotic dynamics, including the change in the number of lynx captured over time in Canada (Figure 3).

Do Populations Have Carrying Capacities?

This question has been addressed using a variety of techniques, including observational types of studies that rely on long-term time series data sets such as the number of lynx captured over time (Figure 3), highly controlled laboratory experiments (Figure 4), and mathematical models to determine potential mechanisms through time series reconstruction. The answer therefore seems to be that carrying capacities do exist for most species but that determining these at any one point in time or space is quite difficult.

Many controlled laboratory experiments have been published that show populations behaving in a fashion consistent with the logistic model (i.e., populations reach a carrying capacity). One of the earliest studies was completed by Gause (1934) (Figure 4). Most laboratory populations tend to increase and then reach some level at which they fluctuate around what might represent a carrying capacity. It is interesting to note that populations rarely exhibit a smooth transition between a growth phase and gradual reductions in growth rate ending in stable populations, despite the controlled environmental conditions. An additional caveat to consider is that prior studies that concluded population growth patterns differed significantly from the expected

Figure 3 The number of lynx trapped in the Mackenzie River district from 1821 to 1934. Reproduced from Elton C and Nicholson M (1942) The ten-year cycle in numbers of lynx in Canada. *The Journal of Animal Ecology* 11: 215–244, with permission from British Ecological Society.

logistic growth likely suffered disproportionately during the review process and failed to make it into print.

Determining how natural populations change over time is surprisingly difficult. The first requisite information necessary to determine whether a population is at or near a constant size, considered here to be a proxy for the habitat's carrying capacity, is simply the population's size over time. This often has to be determined over long periods of time in ways that are accurate, reliable, and repeatable. In field studies, it is rare to have the luxury to repeatedly estimate population size, a technique allowing us to assess the accuracy of our estimates. Determining population size fluctuations may represent real changes in population size or may represent either natural variability (statistical "errors") or actual errors in our estimates.

Assuming, we overlook these shortcomings in our data, what do populations do? In general, populations usually

fluctuate over time. We may be able to correlate these changes with biotic or abiotic factors or some function of the two with time. Sometimes the fluctuations cannot be distinguished from random noise. Some populations, including the classic examples of lynx, hares, and lemmings, cycle periodically (Figure 3). The persistence of population cycles over long periods of time has led to great speculation regarding the factors that might lead to periodicity. Recent work suggests that simple causal mechanisms of cycling are unlikely and that a combination of random environmental factors and non-linear, density-dependent factors influence populations.

Determining the Carrying Capacity of a Population

Determining the carrying capacity of any particular population at a particular time is not trivial. Many different techniques have been suggested and tested, including three primary techniques that can be used to attempt to detect a change in population growth rate as a function of population size: Mathematical modeling of specific mechanisms, tactical experimental tests in the laboratory and field, and statistical analysis of time series data. Ultimately, a combination of these techniques will enable us to understand the importance of regulation in populations and the degree to which populations appear to be governed by a carrying capacity. The author has already discussed the importance of the logistic equation and will briefly introduce the empirical approaches.

There has been much interest in the work that is completed to determine what factors regulate the change in growth of populations over time. The factors that slow population growth rate change over time and from location to location and differ for different species. Regulating factors also are likely to interact with each other, thus complicating the determination of a population's carrying capacity.

In a classic study, Davidson and Andrewartha (1948) used a partial regression technique to analyze an experiment designed to test the relative influence of biotic and abiotic factors on regulating a small herbivorous insect population. They concluded that 78% of the population variance was due to abiotic or weather-related factors. In particular, the number of individual thrips in the spring was related mostly to the preceding autumn's climate. This study was influential because it provided strong evidence that this population of thrips was regulated not by biotic factors such as competition or predation but rather by abiotic factors.

A second method used to detect the presence of density dependence on population regulation is the analysis of time series data. The best data are those that have been collected over consecutive years and that exceed the periodicity of both observed environmental and population fluctuations (generally > 10 years). These data can be subjected to tests that investigate the relationship of change from year to year as a function of the population during the previous year or years in order to detect whether the population appears to be regulated. Such analyses, however, are unable to provide any information on the underlying mechanisms that might lead to population regulation. Therefore, time series analysis is an excellent exploratory tool that can be used to investigate the possibility that a population is regulated. This information can then suggest experiments designed to partition variance among potential candidate mechanisms.

Determination of a population's carrying capacity is best done through a combination of modeling, experimentation, and time series analysis. Research efforts, however, need to be directed toward investigating the underlying mechanisms that govern population regulation. Without an understanding of the relative importance of these regulating factors, it will be difficult to determine whether populations are regulated and whether we can detect a population's carrying capacity.

Current Research on Carrying Capacity

Two main areas of research continue to drive our quest to understand population regulation and the strength and importance of carrying capacity. The persistence of these questions indicates the need to clarify the mechanisms that influence population change over time.

Determining the Relative Strengths of Factors that Regulate Populations

Although some researchers have argued that populations are unregulated, most agree that negative feedback mechanisms operate on populations, resulting in decreased growth at high densities. This may occur through changes in the abundance of food, through increased predation or disease, or through a combination of these biotic factors and abiotic factors such as local climate. These factors may reduce birth rates or increase death rates, or both. Although there are circumstances in which these rates change at low population densities (e.g., the Allee effect, which states that very small populations are likely to decrease due to such factors as difficulty in finding mates or

pollen limitation), their regulation at high densities is likely to be common. This change in birth and death rates as a function of density is referred to as "density dependence."

A population that is regulated has intrinsic, extrinsic, or a combination of these factors that slows population growth. Under such conditions a population's per capita growth rate decreases with increasing population size through reduced birth rates and/or increased death rates. This relationship, in logistic growth, is assumed to be linear. The existence of a carrying capacity, however, is not dependent on the shape of this function, so the violation of this linearity assumption does not weaken the concept of carrying capacity. A better understanding of this relationship, generally determined through carefully designed experiments, will help us understand the importance of regulation on population dynamics.

Krebs *et al.* (1995) suggested that hare and lynx cyclic population dynamics are likely influenced by different sets of factors, including food availability and predation driving the dynamics of hare populations while the lynx population is driven primarily by changes in the number of hares. In a more highly controlled experiment using three trophic levels, Hartvigsen *et al.* (1995) determined that plant performance was controlled by the interaction of top-down and bottom-up factors, including the level of plant resource availability and the presence or absence of herbivores and herbivore predators. These studies suggest that complex, interacting biotic and abiotic factors likely influence population dynamics.

Determining Population Carrying Capacity

The logistic growth equation attempts to model, regulated population change over time and relies on several important assumptions, including the absence of time lags (population dynamics is independent of prior events), migration or immigration, genetic variability or selection, population age structure, and the fact that density dependence is linear (each individual added to the population has a similar effect on the population's per capita growth rate). Violations of these assumptions have been found in various populations and have led to more refined, realistic, and complicated forms of the logistic equation. In addition, the model assumes that the carrying capacity (K) is constant over time and space. This assumption occasionally may be valid in situations in which a population is regulated by habitat availability. This might occur, for example, where the number or area of nesting sites is fixed. It is easy to conjure up situations, however, where this assumption would be violated over very small spatial or temporal scales. It is not likely that K would be constant since populations are usually limited by resources, competitors, enemies, and often combinations of these factors that vary with the environment over time. Under these conditions, changes in resource availability can influence population size directly or indirectly through its often nonlinear effect on the population of competitors and/or predators.

In addition, there is great concern about the stability and persistence of threatened and endangered species (*see* The Importance of the Concept of Carrying Capacity to Biodiversity). Work in this area has begun to recognize the importance of species interactions, immigration and emigration

among subpopulations, the introduction of exotic species, and other factors that violate the assumptions of simple logistic growth. The movement of individuals among subpopulations enables the possibility of increased long-term persistence of populations by reducing large-scale fluctuations and the spreading of risk that a species will become extinct in the event that a single local population disappears (becomes extirpated). This area of research, referred to as “metapopulation biology,” involves determining long-term viability of these subdivided species, and there is currently much research activity in this area.

The Importance of the Concept of Carrying Capacity to Biodiversity

The concept of carrying capacity suggests that species are likely to have some upper limit to their population. If the upper limit is “hard,” then we expect populations to achieve this state and remain relatively constant. Populations, however, as demonstrated in **Figures 3 and 4**, do not behave in such a simple fashion, but have rather “soft” limits. As such, populations usually exhibit random, cyclic, or chaotic dynamics. These dynamics generally lead to increased chances that populations will reach the absorbing state of zero (become either locally extirpated or globally extinct).

We must be concerned about the dynamics of relatively small populations over time. The probability that a population will go extinct is generally related to the degree to which it fluctuates (population amplitude and frequency). Therefore, processes that cause populations to increase fluctuations are likely to lead to species loss and associated reductions in biodiversity. Thus, conservation efforts may be needed that will buffer populations and associated habitats from extreme fluctuations. Conservation efforts are often directed toward increasing a population’s carrying capacity. It should be kept in mind, however, that constant environments also may lead to species losses. The intermediate disturbance hypothesis has gained much empirical support and suggests that the maximum number of species that an area can support occurs when disturbances are intermediate in either frequency or impact. We should be concerned that our management efforts do not reduce the carrying capacity of target species.

The Human Carrying Capacity

The best estimates of human population indicate that it has continued to grow exponentially over recorded history, although the actual growth rate has changed over time. Attempts to fit data on the human population to the logistic equation have failed (**Figure 1**), and current indications are that no human carrying capacity can be predicted from simple population statistics. However, we might ask whether our population growth rate is likely to slow down in the foreseeable future and, ultimately, reach a stable carrying capacity or whether it will overshoot its carrying capacity and eventually collapse.

Cohen (1995) found that estimates of the human carrying capacity have ranged between 1 billion and 1 trillion people,

with the majority of estimates falling between 4 and 16 billion (the current population is about 6 billion). These estimates suggest that we are approaching an apparent limit for our species. Regardless of which estimate seems most appropriate as an upper limit for humans on Earth, the growth rate of our population will eventually slow to ≤ 0 . This can occur as a result of increasing death rates and/or decreasing birth rates. It is predicted that as our population grows in the coming decades there will be an increase in mortality due to diseases. The effect of disease agents on controlling population growth will likely increase due to increases in human contact rates and rapid transit, increasing evolution of drug resistance, and increasing virulence rates. These factors also may reduce birth rates, which of course presents a more pleasant alternative to slow population growth.

Can a population crash be avoided? The author ventures the guess that one cannot. Any long-term stabilization of the human population will require a decrease in the current global birth rate. We certainly cannot hope to achieve a relatively stable population without invoking a substantially higher death rate than the current rate, which is not a comforting thought. It is difficult to imagine, however, that the influence of disease will operate in a simple density-dependent fashion. Instead, it seems more plausible that diseases will “break out” more often with increasing population size and with larger-scale consequences, bringing about a strong reduction in our population – a response seen in many other populations that have increased beyond their carrying capacities.

One last area of hope is that individuals will lower their consumption rates, thereby adjusting the human carrying capacity. It is unlikely that Earth can support tens of billions of people with lifestyles matching those of people in the developed nations such as the US. Therefore, there remains a chance that changes in human behavior will allow our population to gently transition toward a sustainable, zero growth rate population.

Conclusions

The concept of carrying capacity has a history that spans at least thousands of years. The formal definition is approximately 150 years old and is generally coupled to the asymptotic population in the logistic growth equation (K). Critics argue that because of ongoing confusion and the multitude of definitions attached to the concept we would be better off simply abandoning the term. One must also be concerned that the term not be used to advance any particular political agenda associated with determining how large populations of any particular species “should” be in particular areas. This entry cautiously suggests that the concept remains useful. Since most populations are likely to be at least occasionally limited by factors that depend on the population’s density, we need to continue advancing our knowledge of how populations behave and use this information to guide the design of laboratory and field experiments aimed at determining the mechanisms that regulate populations. Only by using the combination of field and laboratory techniques, grounded in a theoretical framework that has roots going back to the simple logistic equation, will we hope to understand and

conserve populations, including our own, over long periods of time.

Glossary

Bionomic equilibrium In a biological common property resource, an equilibrium between resource production rate and exploitation rate, characterized by the dissipation of economic rents.

Commons (or common property resource) Any resource asset that is not privately owned and controlled.

Discount rate Rate (usually annual) at which future revenues are discounted to calculate a present value. Personal discount rates often exceed market rates by a wide margin.

Economic rent The flow of net economic benefits (revenue minus costs) derived from the exploitation of a resource asset.

Externality Cost or benefit imposed on others as the result of some economic activity.

Pareto efficiency An economic equilibrium is Pareto efficient if any change will decrease the economic well-being of at least one participant.

Tragedy of the commons Process whereby a commons is overexploited because individual users cannot expect to realize the potential benefits of resource conservation.

In medieval England the term “commons” referred to an unfenced area of land that, although privately owned (usually by the local manor lord), was by tradition available to specific persons (the commoners) for specific activities, such as pasturage or removal of building materials. The subsequent enclosures of the commons, for the sole benefit of their owners, reduced many former users to penury. In recent times, and especially following the publication of the famous article “The Tragedy of the Commons” (Hardin, 1968), the term has been used to refer to any resource asset that is not privately owned and controlled. This is the sense in which the term commons, synonymous with “common property resource,” will be used here.

Introduction

Important contemporary examples of common property resources include the global atmosphere, the oceans, large lakes, rivers, forests, and fish and wildlife populations, including birds. Though not inevitable, the overexploitation of common property resources is always a potential threat, and often a frightening reality. Many current environmental problems can be traced to the working of a so-called tragedy of the commons.

The classification of resources as either common or private property is an oversimplification. Many gradations exist between a total lack of access restriction (i.e., open-access) and complete individual control. For example, coastal marine resources within 200-mile fishing zones are now recognized as being under the sole jurisdiction of the coastal state, with foreign fishermen either excluded or subject to payment of fees. These resources are thus limited access, but (unless privatized) still common property by our definition. Also, private landowners seldom have full rights to do as they wish with their property – the state may retain mineral rights, for example, and zoning regulations may restrict land use and development.

The logic of the tragedy of the commons is straightforward, as will be explained later. Unfortunately, however, much of

what has been written about common property resources suffers from vagueness and imprecision, leading to unnecessary confusion and controversy. The following hypothetical example can be useful as a basis for a general understanding of the economics of a commons.

Imagine a small lake, completely surrounded by the properties of two landowners. The lake contains a population of fish, and both landowners are avid fishermen. What will be the long-term outcome? The answer is not obvious and depends on various factors.

The first possibility is that the lake is so large, and the fish population so productive, that no amount of fishing by the two landowners has any appreciable effect on the population. In this ideal situation, by assumption nothing happens – the tragedy of the commons does not occur.

The opposite case is more instructive. Suppose, for example, that upon first taking up their properties, the two neighbors are able to catch all the fish they want. After a few years, however, they observe that fish are becoming more scarce. Also, the big ones that used to put up such a fight seem to have disappeared. Subsequent developments now depend on how the two landowners react. If they meet on amicable terms and agree to restrict their catches, or to return some of them to the lake, the dynamics of the exploited fish population may stabilize, permitting sustained if limited catches by both owners. It may take several years of trial and error before the maximum sustainable catch is determined – or they may decide to forego the maximum catch in favor of maintaining a large population of large fish.

An alternative solution might be to subdivide the lake into two fishing zones, one for each landowner. But this assumes cordial relations between the landowners, with each cooperating in not fishing in the other's zone. If fish are able to swim freely between zones, such an agreement may fail to prevent overfishing. Privatization of property or resources is not always feasible, and when it is feasible it presumes mutual trust and cooperation, or external enforcement.

Instead of such amicable agreements, however, the owners may begin blaming each other for overfishing. Relations may

then deteriorate, with both determined to catch all the fish they can find. One may buy a faster boat, hoping to outdo his neighbor, who then responds in kind, and so on. Such behavior between two neighboring individuals may seem petulant. But what if instead of two property owners, there were 100 cottages on the lake, all owned by avid fishermen? Besides increasing the pressure on the fish population, this would make the problem of agreeing over and enforcing catch restrictions much more difficult. Cheating by individuals would be hard to detect, and even harder to control.

This simple example illustrates many of the characteristic features of common property resources, including potential overexploitation, the necessity of mutual cooperation, and the increased difficulties of control as the number of joint owners increases. The author returns to these questions later.

Theory

The theory of a common property renewable resource will be discussed here in terms of a specific example, a commercial fishery. The results and predictions apply, however, to most other biological resources, with minor modification.

The theory of bionomic equilibrium in an unregulated, open-access, common property fishery was initiated by Gordon (1954) (Figure 1). Fishermen exert fishing effort E on a certain fish population; fishing effort is a measure of fishing intensity, for example, the number of vessel-days per year, or (in a rod-and-reel fishery) the number of rod-hours per year. Figure 1 shows the total sustained annual revenue R and total cost C as functions of effort E . Cost increases in proportion to E , but revenue rises to a peak ("maximum sustainable yield") and then declines at higher levels of effort. An input-output function having this inverted-U shape is unconventional in economic theory; it reflects the underlying biology of the resource, which becomes increasingly unproductive as it is depleted by high levels of fishing effort.

Figure 1 Gordon's (1954) model of equilibrium revenue R and cost C in a fishery; $\bar{E}$ = bionomic equilibrium; E^* = effort level for maximum sustainable economic rent. Reproduced from Gordon HS (1954) The economic theory of a common property resource: The fishery. *Journal of Political Economy* 62: 124–142.

Gordon's prediction is that the fishery will reach an equilibrium, called the bionomic equilibrium, at the effort level $\bar{E}$ where revenues and costs are equal. The argument is as follows. First, for $E < \bar{E}$, revenue exceeds costs and fishermen are making money in excess of their opportunity costs. This positive net revenue attracts additional entrants to the fishery, resulting in an increased effort level. On the other hand, if $E > \bar{E}$, fishermen are losing money and some will leave the fishery. Equilibrium can only occur where $E \equiv \bar{E}$. At this bionomic equilibrium the fishermen are barely breaking even financially. (See Clark 2010, for mathematical representation of these ideas.)

For levels of E below $\bar{E}$, revenues R exceed costs C ; the excess $R - C$ is called economic rent. Gordon's prediction can then be stated: in an open-access unregulated fishery all potential economic rents will be dissipated in long-run bionomic equilibrium. Additional predictions are that if the price of fish increases, or if the cost of fishing decreases, the effort level $\bar{E}$ will increase, resulting in a more depleted fish population. What would normally be recognized as benefits to the fishing industry (higher prices, lower costs) are dissipated because of the tragedy of the commons.

What is not clear in the Gordon model is whether the fish population will survive in the long run, or be driven ultimately to extinction. In practice, very few fish species have been fished to extinction, although some marine mammals have been. On land, America's most abundant bird species, the passenger pigeon, was hunted to extinction in the nineteenth century. Today species such as rhinoceroses, tigers, and certain birds are endangered by market hunters. If we agree that the Gordon theory applies to any such commons, then any species is likely to become endangered if the value of the last specimen caught exceeds the cost of capturing it. In a world of extremely affluent consumers and destitute hunters, this condition applies to an ever-widening class of wild species, both marine and terrestrial.

Gordon also identified the effort level E^* yielding maximum economic rent (see Figure 1). He pointed out the apparent anomaly that if the fishermen would only work less hard – reduce their effort – they would be better off! This argument may seem compelling, but the reality is that many, if not most, marine fisheries today remain closer to bionomic equilibrium than to rent maximization. It often seems as if the fishing industry is determined to suffer the tragedy of the commons even though impoverishment is the inevitable outcome. What explains this phenomenon?

To address this question we must consider the dynamics of the fish population (recall that Figure 1 pertains only to equilibrium situations). For example, suppose that a certain fishery is currently at bionomic equilibrium $\bar{E}$. A reduction of effort is needed in order to improve the situation. Unfortunately, such a reduction of effort will not lead to an immediate increase in catches – quite the reverse. At first catches will decrease, more or less in proportion to the decreased effort. The decreased catches will (it is hoped) allow the fish stock to increase over time. Eventually a new equilibrium will be reached, combining reduced effort with increased catches and increased rents. A simulated illustration of this process is shown in Figure 2.

The principal message from the argument is that resource conservation necessarily involves a sacrifice of potential

Figure 2 Simulated annual catches following a reduction in effort at time $t_0 = 10 \text{ yr}^{-1}$. At first catches are reduced, but eventually catches increase to a higher level than before, as the fish population recovers from overharvesting. (Discrete logistic model; $r = 0.3 \text{ yr}^{-1}$, $K = 100,000$ metric tons, $E_{t < t_0} = 0.24 \text{ yr}^{-1}$, $E_{t > t_0} = 0.15 \text{ yr}^{-1}$.)

current benefits in order to achieve greater future benefits. From the economic point of view, conservation is thus a form of investment in the future.

We also see now why management of a common property resource is likely to be difficult: the resource users must agree to make the necessary sacrifice (investment). Moreover, all resource users must then somehow be prevented from overexploiting the protected resource, even though such activities would be individually profitable. The more successful the management program, in terms of protecting the resource, the greater will be the incentive for excessive exploitation by individuals. This dilemma is the real tragedy of the commons.

Although formulated here in terms of fish populations, the concepts of bionomic equilibrium and rent dissipation in common property resources are widely applicable. Overgrazing of grasslands, desertification, deforestation, soil erosion, and pollution are other important examples of overexploitation of the commons. Everywhere that resource stocks are used as common property, the incentive for the commons tragedy exists.

The participants in a tragedy of the commons are sometimes said to be motivated by short-term financial considerations – with “everyone following their own short-term interest” to quote from a recent publication. This portrayal of such resource users as greedy, short-sighted souls is often both unfair and inaccurate (although there probably is a tendency for such individuals to gravitate toward unregulated resource industries). In a commons situation, it is in each participant’s best interests to get as much as possible out of the resource

before it is depleted by others. Any personal sacrifice for the sake of resource conservation is simply dissipated by the other users.

Regulated Bionomic Equilibrium

How can the problems of common property resource exploitation be overcome? Let us first consider an approach that often does not, and perhaps cannot, succeed. Again, imagine a fishery initially at bionomic equilibrium (this is not essential for the discussion). A government agency is set up to manage the fishery. Realizing that the problem is excessive effort in the fishery, the managers introduce a limited-entry program, in which only a fraction of the previous participants are licensed to catch fish. (It goes without saying that, unless compensated in some way, the excluded fishermen will tend to resist this program.) At first the new system may appear to be successful – effort decreases, the fish population begins to recover, catch rates go up; the remaining fishermen are making money.

But now the economic dynamics of the commons begin to operate once again. By increasing their own levels of effort, individual fishermen can increase their current income. Some of the fishermen buy bigger boats, forcing others to do the same in order to compete. The managers must now bring in regulations to restrict the size of fishing boats. The owners then respond by “capital stuffing” – installing larger engines, more powerful winches, better electronic devices, and so on, all of which increase the fishing power of their vessels. These items in turn must then also be regulated. Eventually either

the regulations become so cumbersome that economic rents are dissipated simply by the complexity of the management system, or else the regulations fail to prevent overexpansion of fishing capacity. In either case, the fishery is now in regulated bionomic equilibrium.

Such regulated bionomic equilibrium can nowadays be seen in many managed marine fisheries. Where the regulations are effective and strongly enforced, depletion of fish stocks may be prevented. In practice, however, the economics of the commons has often proved more powerful than the regulations. In a number of cases, intensively managed fisheries have collapsed from persistent overfishing, cod and groundfish on the Atlantic Coast of the United States and Canada being notorious examples. In most of these cases, the fishing industry itself persistently and adamantly opposed the imposition of the regulations that were required to preserve the fishery.

While all of this may seem quite irrational (unless you understand the economics of the commons), in actuality the situation is often more complicated – and more perverse – than described here. To be specific, resource industries are often highly subsidized. Individuals can only benefit from the subsidy if they participate in exploiting the resource. The effect of the subsidy is to reduce the opportunity cost C , in extreme cases to near zero. The Gordon theory explains what happens: bionomic equilibrium corresponds to virtual resource extinction in such a situation. Exploiters become dependent on the subsidy, not the resource. Bionomic equilibrium is more devastating with subsidies than without them.

In the case of Canada's Atlantic cod fishery, the system of regulated, subsidized bionomic equilibrium proceeded to the ultimate conclusion with the almost complete disappearance of cod stocks in 1991. This collapse destroyed the basis of the economy of the entire province of Newfoundland; since 1991 the Canadian government has been paying over \$1 billion per year as welfare to displaced Newfoundland fishermen and plant workers. Whether the Newfoundland cod will ever return is uncertain at the present time (2010).

The management of fisheries that take place outside the 200-mile zones of any coastal state is even more difficult, for lack of jurisdiction. International agreements have sometimes succeeded in preventing overfishing, but the overall picture remains bleak for these truly common property resources.

Managing Incentives versus Managing Resources

Two general approaches to the management of common property resources can be identified: those directed toward management of the resource stock and those that alter the incentives of resource users. Methods aimed at managing the resource include total annual catch quotas, controlled access to the resource, restrictions on the technology of harvesting the resource, and so on. Methods that rely on altering the economic incentives of common property resource exploiters include user fees or royalties and individually allocated quotas (see the following). These methods may also be used in combination. As indicated by the foregoing discussion, management strategies that do not alter users' basic incentives tend to result in regulated bionomic equilibrium, with excessive

inputs and persistent rent dissipation. Methods that alter incentives have the potential of overcoming these difficulties, although the persistent incentive to cheat must be recognized, and countered by monitoring and strict enforcement of the rules.

A third approach, privatization of the resource – usually involving geographical subdivision into individually manageable units – may be considered the ideal solution, since it allows users to become independent of each other and of excessive government interference. This is historically the usual method for dealing with nonfugitive resources, such as land and minerals. Such subdivision and privatization is not feasible, however, for many of today's remaining common property resources. In such cases, some form of centralized management seems necessary. We first consider the case in which the resource is located within the jurisdiction of a single state; the case of international common property resources is discussed in the section International Common Property Resources.

Allocated Quotas

One method of altering the incentives of resource users is a system of allocated quotas, often sold under auction to the highest bidders. This method is commonly used in logging in national forests and in offshore oil drilling.

Having obtained such a quota, the users' incentives are to harvest the quota at minimum cost. Persistent incentives toward cheating are thwarted by rigorous enforcement of the quotas. Resource rents are preserved, and divided between resource users and the government. The resource remains common (state) property, but specific user rights are privatized through the system of quotas. Multiple uses of the resource, as in national forests used for both timber production and recreational activities, can be achieved, although different user groups may attempt to influence management decisions in their favor.

The establishment of 200-mile national fishery zones in the 1980s rendered coastal marine resources subject to quota-based management systems, and individual catch quotas are indeed now in use in many such fisheries. Marine populations, however, provide unusual management difficulties, not the least of which is the fact that these resources are largely hidden from view until they are brought to the surface by net or hook. Also, fish populations undergo major natural fluctuations, which are poorly understood and hard to predict. In addition, many fish populations migrate, with migration routes that change in response to oceanic conditions. These features introduce large, irreducible levels of uncertainty into fisheries management; the author discusses this topic further in the section Risk and Uncertainty.

International Common Property Resources

As an important example of an international common property resource, let us briefly consider the atmosphere. Although partitioning of the atmosphere is clearly not possible, policies at the national level have had significant effects on

atmospheric pollutant emissions. Norway, Sweden, Denmark, France, and Japan have employed taxes on the emission of sulfur dioxide since the 1970s. Some countries now use tradable quotas to control atmospheric emissions. Such policies affect incentives, and are thought to be far more efficient than direct quantitative regulations.

At the international level, over 100 nations have now ratified the 1987 Montreal Protocol requiring the phasing out of ozone-depleting chlorofluorocarbons and related substances. This example shows that, when evidence of severe harm is strong, international cooperation can be achieved. However, the example also illustrates the difficulties, especially at the international level, associated with common property resource management, as noncompliance, failure to ratify, and the proliferation of illegal trade in ozone-depleting substances have persisted. Although no international agency exists to enforce the Protocol, trade sanctions (or the threat thereof) have been used to encourage adherence to the rules.

Similar agreements, and methods of encouraging nations to follow them, apply to other international resource problems, such as greenhouse gas emissions, marine resource exploitation, ocean pollution, and the conservation of migratory birds. Although international management may lag behind the need, it is encouraging that the general principles of managing the commons do appear to be having an effect on the way in which the rules are being written.

Discounting the Future

The view is sometimes expressed that privatizing a commons will automatically result in its conservation. Some economists have gone so far as to assert that the private owner of a renewable resource asset would never overexploit it, except perhaps as a result of miscalculation. This assertion is entirely false and is based on a failure to understand the economic dynamics of natural resource stocks.

To summarize the argument in a nutshell (see [Clark, 2010](#) for details), the hypothetical owner of a renewable resource will calculate the total discounted present value of various options, including sustainable harvesting and depleting the resource for an immediate gain. Managing a certain resource sustainably might, for example, produce an annual income I , whereas eliminating the resource stock could yield an immediate gain P . The present value of the perpetual income stream I is equal to I/i , where i is the annual discount rate. If it happens that P is larger than I/i , it will be more profitable to deplete the resource. By investing the proceeds at interest rate i , the owner will obtain a greater income than by harvesting it sustainably.

Many biological resources, such as whales, trees, and soil, have low annual rates of productivity, often less than 5% per annum. Removing more than 5% of the stock each year will deplete the resource, eventually to extinction. If the resource owner discounts future revenues at more than 5% per annum, he or she may deliberately choose to eliminate the resource for short-term gain.

Resource users may have reasons for discounting future income at rates higher than market interest rates. For example, they may need, or desire, an immediate cash flow. In addition,

the future of the resource may be uncertain, enhancing the relative value of current harvests. Whatever the reason, a resource owner may decide to practice less conservation than may be consistent with sustainable use of the resource.

The same calculation applies to multiple users of a managed common property resource. It is a notorious fact, for example, that the fishing industry almost always demands larger quotas than recommended by government managers. The managers' calculations may be based tacitly on zero discounting, but the industry almost always prefers to receive its income now.

Community Control

A subsidiary theme in the common property resource literature proposes that common property can be a good thing, not necessarily the stage of a tragedy. The idea is that if all so-called "stakeholders" can be assured a voice in the management of the resource, then agreement to achieve the optimum exploitation should follow. Doubtlessly this could be true in a tightly knit society in which defectors face ostracization or other severe penalties. Recent attempts to reach compromise agreements between users of forests or fisheries, however, have proven frustrating. The hypothetical example of the lake with two adjacent property owners suggests that resource conservation can depend strongly on individual behavior. Although decentralization can sometimes bring benefits, the likelihood that community control of biological resources will improve the prospects for conservation needs to be assessed critically in each instance.

As described earlier, individual community members may discount the future to such an extent that the results differ little from the tragedy of the commons. Also, if there is any likelihood that some users will try to take more than their share of the resource, community control can quickly degenerate into a destructive commons scramble. Always a master of the rapier phrase, [Hardin \(1994\)](#) labeled those who preach the doctrine of community control as "commonists." In some cases, community control might resolve a local tragedy of the commons, but the number of individuals involved has to be fairly small, and all outsiders must be excluded. Furthermore, the community probably needs to be homogeneous in tradition and religion.

Risk and Uncertainty

Risk and uncertainty are important in the management of many resources, including common property resources. Here, the following terminology is used: Risk occurs when the outcome of some process is not known in advance, but the probabilities of the various possible outcomes are known from past experience. Uncertainty occurs when these probabilities are not known, or not known accurately. Uncertainty can be reduced through experience and research, but in most situations it cannot be eliminated entirely, that is, it cannot be transformed into pure risk. Examples of irreducible uncertainty are common in resource management. To mention one example, we do not know for certain whether current global warming is the result of increased levels of greenhouse

gases, nor do we know what impact greater concentrations of these gases will have.

In the case of fishery resources, uncertainty persists regarding current stock levels, relationships between stock and recruitment, and the overall effects of exploitation on future stock levels. Furthermore, marine ecosystems are not well understood, meaning that the implications of harvesting certain species cannot be predicted with certainty. In addition, uncertainty pertaining to future environmental conditions, such as global warming, only adds to the difficulty of foreseeing future trends in marine populations.

Reducing uncertainty (e.g., through scientific research), or reducing the effects of uncertainty (e.g., by adopting conservative harvest strategies), can be considered as forms of investment in maintaining the future viability of a renewable resource. The tragedy of the commons operates here as well – under common property conditions, resource exploiters ignore future uncertainties as they attempt to maximize current revenues from the resource. Management strategies that limit resource exploitation on the basis of scientific uncertainty are widely unpopular with fishermen and other common property resource users. Indeed, the argument is often advanced that uncertainty implies that the need to restrict resource use has not been proved. In truth, exactly the opposite is probably true – uncertainty implies that resource use should be limited in a precautionary way.

Biological Reserves

One response to the ever-growing pressure on biological commons is the establishment of protected biological reserves. While the benefits of reserves are apparent in terms of protecting biodiversity, the potential direct economic benefits of reserves have until recently been less appreciated. For example, large-scale marine reserves could help in preventing severe overexploitation, or collapse of important marine resources. Such marine reserves should be thought of as complementary to, rather than as substitutes for, other types of resource management. Unlike other management strategies, however, reserves can provide a positive, potentially “fail-safe” backup to traditional resource management.

Related Concepts

Closely related to the concept of a commons is the economist’s concept of externalities (sometimes called spillover effects). An externality is a cost or benefit imposed on others (without compensation) as the result of some economic activity. Externalities can be positive (e.g., a homeowner paints her house to protect it from the weather, and neighbors enjoy the color scheme) or negative (smoke from the homeowner’s fireplace chokes her neighbor). Users of common property resources impose negative externalities by reducing the stock of the resource available to other users. Environmental pollution is another common example of a negative externality.

In this case, the quality of a resource, rather than the quantity, is reduced by pollution.

Another related economic concept is that of social cost. When a negative externality occurs, the agent that causes the externality incurs a personal cost (his or her private cost) that is less than the total social cost of the activity.

Yet another notion is that of free riders. When the users of a common resource agree to limit their individual impacts, others – the free riders – may continue to exploit the resource. Examples include poachers who illegally slaughter wildlife in protected areas, or nations that fail to ratify or honor international agreements. The dilemma here is that the greater the success in managing the commons, the greater is its attraction to free riders. The problem of free riders explains the dual difficulties inherent in community control of the commons: exclusion of outsiders, and control of cheating by insiders. The failed experiments of national communism serve as strong warnings against undue optimism in these situations.

A basic theoretical prediction of economics, that competitive equilibria are Pareto efficient, is valid only in the absence of externalities. How to remedy the effects of negative externalities is the subject of welfare economics. The immense literature in this field cannot be succinctly summarized, but it can be stated that no fully satisfactory solution to the tragedy of the commons (negative externalities, if you prefer) has been discovered, and it may be that none exists. If not, the commons dilemma promises to become ever more serious as the world’s population continues to grow and exert increasing pressures on the biological systems that are essential to our very survival.

Glossary

Common-pool resources Resources that include all ecosystems that are large enough such that excluding potential beneficiaries from their use is a nontrivial task and each individual's consumptive use (e.g., harvesting of a boatload of fish or a truckload of forest products) reduces what is available to others.

Governance systems Sets of rule configurations used to govern human–ecosystem relationships at operational, collective-choice, and constitutional levels of analysis.

Polycentric governance arrangements Complex, multitiered governance systems in which there is no single center of authority.

Public goods Outcomes that are widely shared and the benefit received by one individual does not reduce benefits available to others.

Rules Commonly understood, normative statements that specify who must, must not, or may take some action or affect some outcome at a particular node in a decision tree.

Introduction

Ecosystems characterized by high levels of biodiversity are complex systems with interactions occurring at multiple spatial and temporal scales. The task of enhancing and sustaining biodiversity through the design of institutions needs to take into account the complexity of the natural systems in which biodiversity occurs. Without effective institutions to limit who can use and regulate diverse harvesting and management practices, common-pool resources can be overharvested and even destroyed. When common-pool resources containing endemic or threatened species are destroyed, the amount of biodiversity in the world is reduced.

When complexity characterizes the nature of the systems to be governed, it is essential to think seriously about the complexity of the proposed governance systems. Without sufficient concern for sustaining complex governance systems, the very processes of regulating behavior to preserve biodiversity will produce the tragic and unintended consequence of destroying the complexity we are trying to protect. In his book *Design for a Brain: The Origin of Adaptive Behavior*, Ashby (1960), an eminent biologist of an earlier era, developed the Law of Requisite Variety. This law can be roughly stated as: Any regulative system needs as much variety in the actions that it can take as exists in the system it is regulating. Translated into the subject of this Encyclopedia, the law of requisite variety could be stated as: Any governance system that is designed to regulate complex biological systems must have as much variety in the actions that it can take as there exists in the systems being regulated. This is a tall order, but it is one to which we need to pay serious attention.

Unfortunately, much of contemporary policy analysis does not base recommendations on the law of requisite variety. Policy proposals related to the preservation of biodiversity tend to focus on two entirely different solutions: (1) the creation of effective market institutions and (2) the creation of national agencies to manage all common-pool resources within a large domain. Both markets and the state are important institutional mechanisms that should be part of the solutions of protecting biodiversity, but not the exclusive mechanisms. A third option, that of combining large numbers

of relatively autonomous local governance systems for specific common-pool resources with larger scale governance regimes – in other words, a polycentric system – has not been given sufficient attention.

This article focuses on monocentric and polycentric forms of regulation. The section Centralized Regimes and Biodiversity discusses the underlying presumption of substantial policy proposals, which is that strong, centralized regimes are essential for managing common-pool resources. Substantial empirical work challenges the validity of this presumption. The section Using Rules as Tools to Change the Structure of Incentives in Common-Pool Resources explores the complexity of using rules as tools to change the structure of commons dilemmas, presents the seven clusters of rules that affect the components of any action situation, and then describes the specific rules that are used in field settings by resource users and government agencies. An examination of the types of rules used in the field yields several important findings. First, the number of rules actually used in field settings is far greater than generally recognized. Second, the type of rules is also different. Boundary rules tend to include as coappropriators of a resource those who are more likely to be trustworthy because they live permanently nearby and have a long-term stake in keeping a resource sustainable. Choice rules define rights and duties that are easy to understand, directly related to sustaining the biophysical structure of the resource, and easy to monitor and enforce. Some rules recommended in the policy literature are not found among the rules used by self-organized systems. This leads to the difficult search for optimal rules, which is discussed in the section The Daunting Search for Better Rules.

Given the complexity of the process of designing rules to regulate the use of common-pool resources, the author argues in the section Experimenting with Rule Change that all policy proposals must be considered as experiments. No one can possibly know whether a proposed change in rules is among the more optimal rule changes, or even whether a rule change will lead to an improvement. All policy experiments have a positive probability of failing. In the section Self-Organized Resource Governance Systems as Complex Adaptive Systems, the author draws on recent research by Holland and

colleagues at the Santa Fe Institute to discuss the attributes and mechanisms of a different form of general organization – a complex adaptive system – that is not the result of central direction. Complex adaptive systems cannot be understood if one tries to fit these systems into the image of an organization with a central director.

The section *The Advantages and Limits of Parallel Sets of Local Users in Policy Experiments* then shows how the parallel efforts by a large number of local resource users to search out and find local rule configurations may find better rule combinations over the long term, whereas top-down design processes are more limited in their capacities to search and find appropriate rules. All forms of decision making have limits. In the section *The Capabilities of Polycentric Systems in Coping with Tragedies of the Commons*, the author discusses the limits of a series of completely independent resource governance systems and the importance of building polycentric governance systems with considerable overlap to combine the strengths of parallel search and design processes with the strengths of larger systems in conflict resolution, acquisition of scientific knowledge, monitoring the performance of local systems, and the regulation of common-pool resources that are more global in their scope. The resulting polycentric governance systems are also not directed by a single center. They, too, are complex adaptive systems requiring policy analysts to change their fundamental views of organization in order to cope more effectively with tragedies of the commons and many of the other problems facing modern societies.

Centralized Regimes and Biodiversity

A substantial number of contemporary policy proposals stress the desirability of central regimes for the regulation of natural resource systems. The scientific management of natural resources, for example, which is regularly taught in many universities to future regulators of natural resources, presents fisheries and forests as relatively homogeneous systems that are closely interrelated across vast domains. This approach, as it has been applied to fisheries management, is described by *Acheson et al.* (1998: 391–392):

For those trained in scientific management, it is also an anathema to manage a species over only part of its range... [I]t is not rational to protect a species in one zone only to have it migrate into another area where it can be taken by other people due to a difference in regulations. Lobsters, for example, extend from Newfoundland to the Carolinas... From the point of view of the National Marine Fisheries Service, it makes sense to have a set of uniform regulations for the entire US coast rather than one for each state.

Contemporary policy analysts also share a belief in the feasibility of designing close-to-optimal rules to govern and manage species over a large domain by utilizing top-down direction. Since natural resources are viewed as relatively homogeneous, and interlinked and simple models exist of how they work, officials acting in the public interest are considered capable of devising uniform and effective rules for an entire region. Prescriptions calling for central governments to impose uniform regulations over most natural resources are thus

consistent with much of contemporary policy analysis (but see the extensive evidence presented in *Poteete et al.*, 2010).

These prescriptions are not, however, supported by extensive research. An extraordinary number of field studies have found that local groups of resource users, sometimes by themselves and sometimes with the assistance of external institutional arrangements, have created a wide diversity of institutional arrangements for coping with common-pool resources when they have not been prevented by central authorities. These empirical studies document successful self-organized resource governance systems in diverse sectors in all parts of the world. Examples also exist of commons dilemmas that have continued unabated. One conclusion that can firmly be made in the light of extensive empirical evidence is that overuse and destruction of common-pool resources is not a determinant and an inescapable outcome when multiple users face a commons dilemma. Scholars have begun to identify the conditions of a resource, and of the users of a resource, that are most conducive to local users self-organizing to find solutions to commons dilemmas. Furthermore, the broad design principles that characterize robust self-organized resource governance systems that have resolved commons dilemmas for long periods of time have been identified (*Ostrom*, 1990) and found basically sound by other scholars (*Cox et al.*, 2010).

Another important set of findings is that national governmental agencies have been notably unsuccessful in their efforts to design an effective and uniform set of rules to regulate important common-pool resources across a broad domain. Many developing countries nationalized all land and water resources during the 1950s and 1960s. The institutional arrangements that local users had devised to limit entry and harvesting lost their legal standing, but the national governments lacked funds and personnel to monitor the use of these effective resources. Thus, common-pool resources were converted to de jure government-property regimes, but reverted to de facto open-access regimes. The perverse incentives of such open-access regimes are often accentuated, since local users have specifically been told that they will not receive any benefits if they adopt a long-term perspective and regulate their use of the resource. When resources that were previously controlled by local participants have been nationalized, state control has usually proved to be less effective and efficient, if not disastrous, than control by those directly affected. The harmful effects of nationalizing forests that had earlier been governed by local user groups have been well documented in Asia and in Africa. Similar results have occurred with regard to inshore fisheries taken over by state or national agencies from local control by the inshore fishermen themselves.

These findings challenge the theoretical foundations of much of contemporary policy analysis. A foundational belief underlying this analysis is that designing rules to change the incentives of participants is a relatively simple analytical task best done by objective analysts not intimately related to any specific resource. Analysts view most resources in a particular sector as relatively similar and sufficiently interrelated, and thus conclude that they need to be governed by the same set of rules. This is bolstered by the view that an organization itself requires central direction. Consequently, the multitude of self-organized resource governance systems are viewed as mere collections of individual agents each out to maximize their

own short-term returns. The groups who have actually organized themselves are frequently invisible to those who cannot imagine organization without rules and regulations issued by a central authority.

To understand why designing rules to regulate the use of common-pool resources so as to sustain their long-term productivity and biodiversity is not a simple task, one has to somewhat change the perspective. One must begin to think through the process of using rules as tools to change the structure of incentives facing users of a common-pool resource.

Using Rules as Tools to Change the Structure of Incentives in Common-Pool Resources

With this change in perspective, we can think of users trying to understand both the biophysical structure of a common-pool resource and how to affect each other's incentives in order to increase the probability of sustainable use over the long term. Instead of being endowed with complete knowledge of how a common-pool resource reacts to use patterns over time, they have to explore and discover the biophysical structure of a particular resource that will differ on key parameters from similar resources in the same region. Further, they have to cope with considerable uncertainty related to the weather, complicated growth patterns of biological systems that may at times be chaotic in nature, and external price fluctuations that affect the costs of inputs and the value of outcomes. In addition to the physical changes that they can make in the resource, seven clusters of rules directly affect the components of their own action situations. This list of rules is the result of many years of theoretical and empirical work on a framework for conducting institutional analyses (see *Ostrom et al.*, 1994: Ch. 2). Specifically, the rules they can change include:

1. Boundary rules affect the characteristics of the participants.
2. Position rules differentially affect the capabilities and responsibilities of those in positions.
3. Choice rules affect the actions that participants in positions may, must, or must not do.
4. Scope rules affect the outcomes that are allowed, mandated, or forbidden.
5. Aggregation rules affect how individual actions are transformed into final outcomes.
6. Information rules affect the kind of information present or absent in a situation.
7. Payoff rules affect assigned costs and benefits to actions and outcomes.

Given the nonlinearity and complexity of common-pool resource situations, it is rarely easy to predict what effect a change in a particular rule will produce. For example, a change in a boundary rule to restrict the entry of users simultaneously reduces the number of individuals who are tempted to break choice rules, but it also reduces the number of individuals who monitor others or contribute funds toward hiring a guard. Thus, the opportunities for rule breaking may increase. Further, the cost of a rule infraction will be spread over a smaller group of users and, thus, the harm to any individual may be greater. Assessing the overall effects of a change in

boundary rules is a nontrivial analytical task. Instead of conducting such a complete analysis, users are more apt to use their intuitive understanding of the resource and each other to experiment with different rule changes until they find a combination that seems to work in their setting.

To understand the types of tools that are available to users somewhat better, the kinds of boundary, choice, payoff, and position rules used in field settings are examined in some detail. These four clusters of rules are the major tools used to affect the management of common-pool resources, whereas information, scope, and aggregation rules are utilized to complement changes induced by these four rules.

For the past two decades, colleagues at or associated with the Workshop in Political Theory and Policy Analysis at Indiana University have studied a very large number of fisheries, forests, irrigation systems, and groundwater basins, as well as other common-pool resources. Colleagues have collected an immense archive of original case studies written by many scholars on all sectors in all parts of the world (*Hess, 1999*). Colleagues have developed structured coding forms to help them identify the specific kinds of common-pool situations faced in the field, as well as the types of rules that users have evolved over time to try to govern and manage these resources effectively. To develop standardized coding forms, colleagues read hundreds of cases describing how local common-pool resources were or were not regulated by a government agency, by the users themselves, or by a nongovernmental organization (NGO).

Affecting the Characteristics of Users through Boundary Rules

The most frequent recommendation concerning boundary rules in the policy literature is to limit the number of persons allowed to appropriate from a common-pool resource so that the level of appropriation is reduced or to require users to obtain a license before harvesting. Boundary rules affect the types of participants with whom other participants will be interacting. If contingent cooperation is perceived to be a possibility, then one of the most important ways to enhance the likelihood of using reciprocity norms is to increase the proportion of participants who are well known in a community, have a long-term stake in that community, and would find it costly to have their reputation for trustworthiness harmed in that community. Reducing the number of users while opening the resource to strangers who are willing to pay a license fee, but who lack a long-term interest in the sustainability of a particular resource, may reduce the level of trust and willingness to use reciprocity and thus increase enforcement costs substantially.

Colleagues have identified 27 boundary rules as having been used in at least one common-pool resource somewhere in the world (*Ostrom et al.*, 1989). Although some systems use only a single boundary rule, many use two or three of these rules in combination. Boundary rules can be broadly classified in three general groups defining how individuals gain authority to appropriate resource units from a common-pool resource. The first type of boundary rule relates to an individual's citizenship, residency, or membership in a particular organization. Many forestry and fishing user groups require

members to have been born in a particular location. A second broad group of rules relates to individuals who have ascribed or acquired personal characteristics. Other user groups may require that appropriation depend on ethnicity, clan, or caste. A third group of boundary rules relates to the relationship of an individual with the resource itself. Using a particular technology or acquiring appropriation rights through an auction or a lottery are the examples of this type of rule. About half of the rules relate to the characteristics of the users themselves. The other half involves diverse relationships with the resource.

In a systematic coding of those case studies for which sufficient information existed about rules related to inshore fisheries in many parts of the world, Schlager coded 33 user groups out of the 44 groups identified as having at least some rules regarding the use of the resource. All 33 groups depended on some combination of 14 different boundary rules (Schlager, 1994: 258). None of these groups relied on a single boundary rule. Thirty out of 33 groups (91%) limited fishing to those individuals who lived in a nearby community, whereas 13 groups also required membership in a local organization. Consequently, most inshore fisheries organized by the users themselves restrict fishing to those individuals who are well known to each other, have a relatively long-term time horizon, and are connected to one another in multiple ways.

After residency, the next most frequent type of rule, used in two-thirds of the organized subgroups, involves the type of technology that a potential fisher must use. These rules are often criticized by policy analysts, since gear restrictions tend to reduce the efficiency of fishing. Gear restrictions have many consequences, however. Used in combination with choice rules that assign fishers using one type of gear to one area of the fishing grounds and fishers using another type of gear to a second area, they solve conflicts among noncompatible technologies. Many gear restrictions also place a reduced load on the fishery itself and thus help to sustain longer term use of the resource.

Other rules were also used. A scattering of groups used ascribed characteristics (age, two groups; ethnicity, three groups; race, five groups). Three types of temporary use-rights included government licenses (three groups), lottery (five groups), and registration (four groups). Seven groups required participants to have purchased an asset such as a fishing berth, whereas three groups required ownership of nearby land. Schlager did not find that any particular boundary rule was correlated with higher performance levels across the groups. She did find, however, that the 33 groups who had at least one boundary rule tended to be able to solve common-pool problems more effectively than the 11 groups who had not crafted boundary rules.

Thus, many of the rich diversity of boundary rules used by users in the field attempt to ensure that the users will be relating to others who live nearby and have a long-term interest in sustaining the productivity of the resource. One way of coping with the commons is, thus, changing the composition of who uses a common-pool resource to increase the proportion of participants who have a long-term interest, who are more likely to use reciprocity, and who can be trusted. Central governments tend to use a smaller set of rules and some of these may open up a resource to strangers without a longer term commitment to the resource.

Affecting the Set of Allowable Actions through Choice Rules

Choice rules are also a major type of rule used to regulate common-pool resources. Colleagues identified a diversity of choice rules used in field settings. Some rules involve a simple formula. Many forest resources, for example, are closed to all forms of harvesting during one portion of the year and open for extraction by all who meet the boundary rules during an open season. Most choice rules, however, have two components: an assignment and a basis. A fisher, for example, might be assigned to a fixed location (a fishing spot) or to a fixed rotational schedule, or a member of the founding clan may be assigned (allowed) to cut timber anywhere in a forest. In addition to the assignment used in a choice rule, most rules required a basis for the assignment. For example, a fisher might be assigned to a fixed location based on a number drawn in a lottery, on the purchase of that spot in an auction, or on the basis of his or her historical use.

If all of the bases were likely to be combined with all of the assignment possibilities, there would be 112 different choice rules (8 assignment formulas times 14 bases). A further complication is that the rules for one product may differ from those of another product in the same resource. In regard to forest resources, for example, children may be authorized to pick fruit from any tree located in a forest so long as it is for their own consumption, women may be authorized to collect so many headloads of dead wood for domestic firewood and certain plants for making crafts, whereas *shamans* are the only ones authorized to collect medicinal plants from a particular location in a forest. Appropriation rights to fish are frequently related to a specific species. Thus, the exact number of rules that are actually used in the field is difficult to compute since not all bases are used with all formulas, but many rules focus on specific products. A further complication is that the rules may regularly change over the course of a year, depending on resource conditions.

Schlager (1994: 259–260) found that all 33 organized subgroups used one of five basic assignments in their choice rules. Every user group included in her study assigned fishers to fixed locations using a diversity of bases, including technology, lottery, or historical use. Thus, spatial demarcations are a critical variable for inshore fisheries. Nine user groups required fishers to limit their harvest to fish that met a specific size requirement, whereas seven groups allocated fishers to fishing spots using a rotation system and seven other groups only allowed fishing locations to be used during a specific season. Four groups allocated fishing spots for a particular time period (a fishing day or a fishing season).

An important finding – given the puzzles addressed in this article – is that the choice rule most frequently recommended by policy analysts is not used in any of the coastal fisheries included in Schlager's study. No attempt was made

by the fishers involved to directly regulate the quantity of fish harvested based on an estimate of the yield. This is particularly surprising given that the most frequently recommended policy prescription made by fishery economists is the use of individual transferable quotas based on estimates on the economically optimal quantity of fish to be harvested over the long run (Schlager, 1994: 265).

In an independent study of 30 traditional fishery societies, Acheson, Wilson, and Steneck also noted the surprising absence of quota rules:

All of the rules and practices we found in these 30 societies regulate [how] fishing is done. That is, they limit the times [when] fish may be caught, the locations where fishing is allowed, the technology permitted, and the stage of the life cycle during which fish may be taken. None of these societies limits the [amount] of various species that can be caught. Quotas – the single most important concept and tool of scientific management – is conspicuous by its absence (Acheson *et al.*, 1998: 397).

Local inshore fishers, when allowed to manage a riparian area, thus use rules that differ substantially from those recommended by advocates of scientific management. Fishers have to know a great deal about the ecology of their inshore region, including spawning areas, nursery areas, the migration routes of different species, and seasonable patterns, just to succeed as fishers. Over time, they learn how

to maintain these critical life-cycle processes with rules controlling technology, fishing locations, and fishing times. Such rules, in their view, are based on biological reality (Acheson *et al.*, 1998: 405).

The diversity of rules devised by users greatly exceeds the limited choice rules recommended in textbook treatments of this problem. Users thus cope with the commons by a wide variety of rules affecting the actions available to participants and, thus, their basic set of strategies. Given this wide diversity of rules, it is particularly noteworthy that rules assigning users a right to a specific quantity of a resource are used so infrequently in inshore fisheries. (They are used more frequently when allocating forest products, where the quantity available, as well as the quantity harvested, is much easier to measure.) To assign a user a specific quantity of a resource unit requires that those making the assignment know the total available units.

Affecting Outcomes through Payoff and Position Rules

One way to reduce or redirect the appropriations made from a common-pool resource is to change payoff rules so as to add a penalty to actions that are prohibited. Many user groups also adopt norms that those who are rule breakers should be socially ostracized or shunned and individual users tend to monitor each other's behavior rather intensively. Three broad types of payoff rules are used extensively in the field: (1) the imposition of a fine, (2) the loss of appropriation rights, and (3) incarceration. The severity of each of these types of sanctions can range from very low to very high and tends to start out on the low end of the scale. Inshore fisheries studied by Schlager relied heavily on shunning and other social norms and less on formal sanctions.

Passing rules that impose costs is relatively simple. The real difficult task is monitoring behavior to ascertain if rules are being broken. Self-organized fisheries tend to rely on self-monitoring more than the creation of a formal position of guard. Most inshore fishers now use shortwave radios as a routine part of their day-to-day operations, allowing a form of

instant monitoring to occur. An official of a West Coast Indian tribe reports, for example, that:

it is not uncommon to hear messages such as 'Did you see so-and-so flying all that net?' over the shortwave frequency – a clear reference to a violation of specified gear limits (Singleton, 1998: 134).

Given that most fishers will be listening to their shortwave radio,

such publicity is tantamount in creating a flashing neon sign over the boat of the offender. Such treatment might be preceded or followed by a direct approach to the rule violator, advising him to resolve the problem. In some tribes, a group of fishermen might delegate themselves to speak to the person (Singleton, 1998: 134).

Among self-organizing forest governance systems, creating and supporting a position as guard is frequently essential, since resource units are highly valuable and a few hours of stealth can generate substantial illicit income. Monitoring rule conformance among forest users by officially designated and paid guards may make the difference between a resource in good condition and one that has become degraded. In a study of 279 forest *panchayats* in the Kumaon region of India, Agrawal and Yadama (1997) found that the number of months a guard was hired was the most important variable affecting forest conditions. The other variables that affected forest conditions included the number of meetings held by the forest council (a time when infractions are discussed) and the number of residents in the village.

It is evident from the analysis that the capacity of a forest council to monitor and impose sanctions on rule-breakers is paramount in maintaining the forest in good condition. Also, the presence of a guard should not be taken simply as a formal mechanism that ensures greater protection. It is also an indication of the informal commitment of the *panchayat* and the village community to protect their forests. Hiring a guard costs money... If there was scant interest in protecting the forest, villagers would have little interest in setting aside the money necessary to hire a guard (Agrawal and Yadama, 1997: 455). Recent findings from the International Forestry Resources and Institutions (IFRI) research program have also shown that the outcome of users themselves monitoring forests is extremely effective (Coleman and Steed, 2009; Chhatre and Agrawal, 2008, 2009).

Boundary and choice rules also affect how easy or difficult it is to monitor activities and impose sanctions on rule infractions. Closing a forest or an inshore fishery for a substantial amount of time, for example, has multiple impacts. It protects particular plants or fish during critical growing periods and allows the entire system time to regenerate without disturbance. Further, during the closed season, rule infractions are highly obvious to anyone as any user in the resource is almost certainly breaking the rules. Similarly, requiring users to use a particular technology may reduce the pressure on the resource, help to solve conflicts among users of incompatible technologies, and also make it very easy to ascertain if rules are being followed. Changing payoff rules is the most direct way of coping with commons dilemmas.

Affecting Outcomes through Changes in Information, Scope, and Aggregation Rules

Information, scope, and aggregation rules tend to be used in ways that complement changes in boundary, choice, payoff, and position rules. Individual systems vary radically in regard to the mandatory information that they require. Many smaller and informal systems rely entirely on a voluntary exchange of information and on mutual monitoring. Where resource units are valuable and the size of the group is large, more and more requirements are added regarding the information that must be kept by users or their officials. Scope rules are used to limit harvesting activities in some regions that are being treated as refugia. By not allowing any appropriation from these locations, the regenerative capacity of a system can be enhanced. Aggregation rules are used extensively in collective-choice processes and less extensively in operational settings, but one aggregation rule that is found in diverse systems is a requirement that harvesting activities be done in teams. This increases the opportunity for mutual monitoring and reduces the need to hire special guards.

It is important to note that repeated studies have not yet found any particular rules to have a statistically positive relationship to performance. The absence of any boundary or any choice rules is consistently associated with poor performance. Relying on only a single type of rule for an entire set of common-pool resources is also negatively related.

The Daunting Search for Better Rules

It should now be obvious that the search for rules that improve the outcomes obtained in commons dilemmas is an incredibly complex task involving a potentially infinite combination of specific rules that could be adopted. To ascertain whether one has found an optimal set of rules to improve the outcomes achieved in a single situation, one would need to analyze how diverse rules affect incentives, strategies, and outcomes. Since there are multiple rules that affect incentives, conducting such an analysis would be an incredibly time- and resource-consuming process. For example, if only five changes in rules per component were considered, there would be 5^7 or 75,525 different rule configurations to analyze. This is a gross simplification however, since some of the important rules used in field settings include more than 25 rules (in the case of boundary rules) and even more than 100 variants (in the case of choice rules). Further, how these changes affect the outcomes achieved in a particular location depends on the biophysical characteristics of that location and the type of community relationships that already exist. No set of policy analysts (or even all of the policy analysts in the world today) could ever have sufficient time or resources to analyze more than 75,000 combinations of rule changes and resulting situations, let alone all of the variance in these situations due to biophysical differences.

Experimenting with Rule Changes

Instead of assuming that designing rules that approach optimality or that even improve performance, is a relatively simple analytical task that can be undertaken by distant

objective analysts, we need to understand the policy design process as involving an effort to tinker with a large number of component parts (see Jacob, 1977). Those who tinker with any tools – including rules – are trying to find combinations that work together more effectively than other combinations. Policy changes are experiments based on more or less informed expectations about potential outcomes and the distribution of these outcomes for participants across time and space (Campbell, 1969). Whenever individuals agree to add a rule, change a rule, or adopt someone else's proposed rule set, they are conducting a policy experiment. Further, the complexity of the ever-changing biophysical world combined with the complexity of rule systems means that any proposed rule change faces a nontrivial probability of error.

When there is only a single governing authority, policy-makers have to experiment simultaneously with all of the common-pool resources within their jurisdiction with each policy change. Once a change has been made and implemented, further changes will not be made rapidly. The process of experimentation will usually be slow, and information about results may be contradictory and difficult to interpret. Thus, an experiment that is based on erroneous data about one key structural variable or one false assumption about how actors will react can lead to a very large disaster (see Wilson *et al.*, 1999). In any design process where there is substantial probability of error, having redundant teams of designers has repeatedly been shown to have considerable advantage (see Landau, 1969).

Self-Organized Resource Governance Systems as Complex Adaptive Systems

As discussed in the section Centralized Regimes and Biodiversity, the very concept of organization is closely tied for many scholars to the presence of a central director who has designed a system to operate in a particular way. Consequently, the mechanisms used by noncentrally directed systems are not always well understood. Many self-organized resource governance systems are invisible to the officials of their own country or those from donor agencies. A classic example of this occurred in the Chitwan valley of Nepal several years ago when an Asian Development Bank team of irrigation engineers recommended a very large loan to build a dam across the Rapti River to enable the farmers there to irrigate their crops. What the engineering design team did not see was the 85 farmer-managed irrigation systems that already existed in the valley and that had achieved relatively high performance. Most farmers in the Chitwan valley already obtained three irrigated crops a year as a result of their participation in the activities of these irrigation systems (see Benjamin *et al.*, 1994). In fact, a study of more than 200 irrigation systems in Nepal found that the farmer-managed irrigation systems outperformed the well-financed agency-managed irrigation systems in regard to economic and technical efficiency as well as equity in terms of delivering substantial water to the tail end of the systems (Joshi *et al.*, 2000).

In contrast to forms of organization that are the result of central direction, most self-organized groups – including the

types of locally organized users of fisheries and forests discussed in this article – are better viewed as complex adaptive systems. These systems are composed of a large number of active elements whose rich patterns of interactions produce emergent properties that are not easy to predict by analyzing the separate parts of a system. Holland (1995: 10) views complex adaptive systems as:

systems composed of interacting agents described in terms of rules. These agents adapt by changing their rules as experience accumulates. Such systems exhibit coherence under change, via conditional action and anticipation, and they do so without central direction (Holland, 1995: 38–39).

Holland points out that complex adaptive systems differ from physical systems that are not adaptive and that have been the foci of most scientific effort. It is the physical sciences that have been the model for many aspects of contemporary social science. Thus, the concepts needed to understand the adaptivity of systems are not yet well developed by social scientists.

Properties and Mechanisms of Complex Adaptive Systems

No general theory of complex adaptive systems yet exists to provide a coherent explanation for processes shared by all complex adaptive systems. Biologists have studied many different adaptive systems but within separate fields of biology. Thus, even biologists have not recognized some of the similarities of structures and processes that characterize the central nervous system, the immune system, and the evolution of species. Recent work at the Santa Fe Institute has begun to identify central attributes, mechanisms, and processes used by all complex adaptive systems including both biological systems as well as markets and other social systems that are not centrally directed.

It appears that all complex adaptive systems share four basic properties: nonlinearity, flows, diversity, and aggregation. The first three properties are self-evident and clearly characterize the types of self-organized resource governance systems discussed in this article. Aggregation refers to the

emergence of complex larger-scale behaviors from the aggregate interactions of less complex agents (Holland, 1995: 11).

For example, many irrigation systems are divided into several tiers and multiple units at each of these tiers. The farmers on a field irrigation channel are responsible for distributing the water to this small channel as well as keeping it in good repair. All farmers whose field channels are served by a branch canal may send a representative to a branch canal organization that focuses its attention on the distribution of water among all branches and on the maintenance of the distribution canals. The branch canal organization may send a representative to a central committee who is responsible for the headworks that divert the water from a river into the system in the first place. The rules used on one branch canal or one field channel may be quite different than on others. There is no single center of authority for these systems that makes all relevant decisions on how to get water from the river to a farmer's field, but in many farmer-organized systems the water is distributed in an

organized fashion and all of the waterworks are maintained as a result of the aggregation of decisions and actions at multiple levels.

In addition to these four attributes, complex adaptive systems also use three mechanisms that are key to the adaptive process itself. These include the use of tags, internal models, and building blocks.

The Use of Tags

Tagging is a universal mechanism for boundary formation and aggregation of units in complex adaptive systems.

Tags are a pervasive feature of (complex adaptive systems) because they facilitate selective interaction. They allow agents to select among agents or objects that would otherwise be indistinguishable (Holland, 1995: 14).

All of the types of boundary rules discussed here involve the specification of the tags that will be used to determine who is authorized to be a co-user from a common-pool resource. Residency, prior membership, and personal characteristics are attributes that already exist and are easy to use as boundary tags. Local governance systems rely heavily on tags that identify individuals who are already known to each other, who have a long-term stake in the sustainability of a resource, who have an incentive to build a reputation for being trustworthy, and who are thus likely to extend reciprocity rather than recalcitrance in dealing with joint problems.

Tags are also used extensively to mark locations in a resource, to warn rule infractors, and even to mark individual organisms that need to be treated in a special way. An example of the latter occurs along the Maine coast, where it is forbidden to harvest berried lobsters (those with eggs). Such lobsters are V-notched and returned back to the sea. Any other fisher who captures a V-notched lobster is also supposed to return it to the sea.

Internal Models

The users from a common-pool resource build internal models of the resource, of the relationships among the components of the resource, and of where their own actions positively or negatively affect one another and the resource. Among the shared lore for most fishing villages is a clear understanding of where fish breed, where young fish tend to cluster, the length of time it takes for fish to be mature and reproduce, the migration patterns of fish, the food chain in a location, and other information. Many inshore fishers develop their own maps of all of the fishing spots in their grounds. In an effort to reduce the interference of one boat with another boat's fishing, these are frequently defined so that if all spots are filled, all boats are still able to have a good chance to catch fish. These maps are then used in a variety of allocation rules that specify the basis for how any particular boat is assigned to a particular fishing spot. Users of forests also map their forests and may create refugia – sometimes as sacred forests – for sections of a forest that are particularly rich in biodiversity. By not harvesting from these refugia, they serve as a source of regeneration to other nearby locations that are disturbed through harvesting.

Building Blocks

Building blocks are ways of breaking down complex processes into small chunks that can be used in multiple ways and combined and recombined repeatedly and at diverse levels. Once a choice rule that allocates resource units on some basis is determined for example, using the same basis again to allocate responsibility for maintenance work is considered to be a fair allocation of benefits and costs in many cultures and is relatively easy to remember. On the large Chhattis Mauja farmer-organized system in Nepal, for example, water was originally allocated by the land area served. In the 1950s, the formula used for maintenance work was that each branch canal was responsible to send one person to work on the main canal for each 17 ha of area it irrigated.

The term used for a person-day of labor for canal maintenance was *kulara*. Since the share of water a branch canal is entitled to receive is the same as the resource mobilization requirement, water allocation is now also referred to as ‘so many *kulara* of water’ (Yoder, 1991: 7).

As the system has grown, the total number of *kularas* has now been set at 177 shared among 44 branch canals. Voting rights are now also set in terms of *kularas*.

Therefore, a branch canal with five *kulara* was entitled to 5/177 of the water in the main canal, responsible to supply 5/177 of the resources mobilized for the irrigation, and had five of the total 177 votes in all important decisions (Yoder, 1991: 7).

Changing Rules as an Adaptive Process

Given the logic of combinatorics, it is impossible – as we showed earlier – to conduct a complete analysis of the expected performance of all of the potential rule changes that could be made by the individuals who are served by a self-organized resource governance system and are trying to improve its performance. A similar impossibility also exists for many biological systems. Let us explore these similarities.

Self-organizing resource governance systems have two structures that are somewhat parallel in function to the concepts of a genotype and a phenotype in biology. Phenotypic structures characterize an expressed organism – how bones, organs, and muscles develop, relate, and function in an organism in a particular environment. The components of an action situation characterize an expressed situation – how the number of participants, the information available, and their opportunities and costs create incentives, and how incentives lead to types of outcomes in a particular environment. The genotypic structure characterizes the set of instructions encoded in DNA to produce an organism with a particular phenotypic structure. A rule configuration is a set of instructions on how to produce the structure of relationships among individuals in an action situation, which is also affected by the biophysical world and the kind of community or culture in which an action situation is located.

The evolution of social systems does not follow the same mechanisms as the evolution of species. As an evolutionary process, of course, there must be the generation of new alternatives, selection among new and old combinations of structural attributes, and retention of those combinations of

attributes that are successful in a particular environment. In evolving biological systems, genotypic structures are changed through mechanisms such as crossover and mutation, and the distribution of particular types of instructions depends on the survival rate of the phenotypes that they produce in given environments. Instead of blind variation, however, human agents do try to use reason and persuasion in their efforts to try to devise better rules, but the process of choice always involves experimentation.

Rule configurations can be represented as a string of symbols that describe which rules are in effect in a particular location. In Table 1, the left-hand column lists a small subset of the rules typically found in the field. A “1” has been entered in a cell of a column to indicate when a specific rule is in use, and a “0” has been entered when the rule is not in use. Thus, the eight columns represent the simplified rule configurations for eight hypothetical locations.

Location A would be characterized as one at which the participants are required both to live in a local community and to use geographic assignments or a rotation system, but also at which there are no formal sanctions used or guards hired to monitor conformance to the entry rules and rotation system. Further, no records are kept, there are no refugia, and users can work individually or in teams. In contrast, Location C creates a refugium in which no appropriation may be undertaken, and does not allocate the remaining space to individual users. If there is a very good breeding and nursery area in this fishery, and it can be well demarcated so that it is obvious if someone has ventured into the refugium by mistake (or by intent), a rule system that does not limit fishing in any

Table 1 Rule configurations and appropriation situations^a

Rule configurations	Locations							
	A	B	C	D	E	F	G	H
Boundary rules								
Local residency	1	1	1	1	0	0	0	0
Member of local coop	0	1	0	1	1	1	1	1
Choice rules								
Spatial assignment	1	0	0	0	1	0	1	0
Rotate in time	1	1	0	0	1	1	0	1
Payoff rules								
Fines	0	0	1	1	0	0	1	1
Loss of rights	0	0	0	0	0	0	1	1
Position rules								
All symmetric	1	1	1	1	0	0	0	0
Guard created	0	0	0	0	1	1	1	1
Information rules								
Infractions are recorded	0	0	0	1	1	0	0	1
Appropriation is recorded	0	0	0	0	0	0	0	1
Scope rules								
Forbidden access to refugia	0	0	1	0	1	0	1	1
Aggregation rules								
Must appropriate in teams	0	0	0	0	0	0	0	1

^aA “1” indicates when a specific rule is in use, and a “0” indicates when the rule is not in use. See text for details.

other way may be a very effective system for protecting the regenerative capabilities of a fishery. It is certainly less expensive than naming specific fishing spots, making an allocation of each fishing team to particular spots, and enforcing a more complicated rule system. At Location C, users also need to live in the local area, and they do face fines if a fellow user notices that they have appropriated from the refugium. Though a guard is not created, records are kept of any infractions noted through the mutual monitoring process.

Location H utilizes a much fuller array of rules. Users must belong to a local cooperative, even though they do not have to live in the local community. Both a refugium and a system for allocating time in which to conduct appropriation have been created, although, with the exception of the forbidden area of the refugium, the latter is not spatially defined. Payoff rules have been modified so that there are both fines for infractions as well as the possibility of losing rights to appropriate, if infractions are substantial. Records of infractions and of the time when someone appropriates are required, and individuals are constrained to working in teams rather than being allowed to appropriate as individuals.

Whether any or all of these rule configurations structured the incentives of users so that participants appropriate from their resource in a sustainable and efficient manner cannot be ascertained from learning about the rules alone. Whether a set of rules enhances performance depends on the structure of the biophysical system in that location and the willingness of participants to follow the rules. Whether the strategy of creating a refugium, as in C and H, works better than the geographic assignment, as in A, depends on how large the refugium is, how rapidly and extensively regeneration from the refugium spreads through the rest of the resource, and how well users understand each of these systems and try to make them work. All three rule systems are likely to work well in some locations and poorly in others.

With this form of representation, we can begin to see how experimentation with rules may be similar to structural changes affecting other types of complex adaptive systems. Most systems are likely to start with one or two very simple rules. An obvious first candidate is to use tags to close the boundary to outsiders so that the likelihood of contingent cooperation and conformance to agreements will be enhanced. By only changing a few rules at the beginning, everyone can come to understand those rules while they are evaluating how they work. A second obvious candidate is to use the shared model of the environment built up through years of interaction in an environment to refine where harvesting should be undertaken and when. Space and time are obvious candidates for allocating access to resources in a manner that is relatively low in cost to sustain. If the community is small enough and shares common norms at a high enough level, creating formal sanctions, guards, records, and other rules may not be necessary. Thus, one can imagine a process in which a rule configuration of mostly zeros slowly converts over time to a scattering of ones and potentially to a rule configuration with many ones.

Changes in specific rules may come about through accident (such as forgetting a rule) or through specific collective-choice processes in which considerable time and effort are devoted to considering why the performance needs to be enhanced and

which rules might be changed. Since many users will have experience with more than one product (e.g., mushrooms from a forest), rules tested with regard to one product may also be applied to others if they are successful. Migration of individuals into a community brings individuals with repertoires of different rules used in other locations. Commerce with other groups lets users see and learn about others who may be doing better (or worse) than them in regulating a sustainable biodiverse and efficient resource system. Thus, a self-organized resource governance system with a higher level of in-migration or greater communication with other localities is more likely to adapt and change rules over time than one in which few new ideas concerning how to use rules as tools are brought into the system. Trial-and-error processes may give relatively rapid feedback about rules that obviously do not work in a particular environment, but this is not always the case when the effect of human action on the environment has a long time delay. If all self-organized resource governance systems are totally independent and there is no communication among them, then each has to learn through its own trial-and-error process. Many will find that rules that they have tried do not work, whereas some will fail entirely.

The rate of change will differ among self-organized resource governance systems. As with all learning, the rate of change is an important variable that affects performance over time. If change occurs too rapidly, little is learned from each experiment before another is launched. Respect for tradition and even religious mystification has been used to increase the retention of rules that are considered by at least some participants to work better. If the heavy hand of tradition is, however, too heavy and squelches innovation, a system that may have been well adapted to a past environment may find itself faltering as external changes occur without internal changes also occurring.

The Advantages and Limits of Parallel Sets of Local Users in Policy Experiments

Let us now discuss why a series of relatively autonomous, self-organized, resource governance systems may do a better job in policy experimentation than a single central authority. Among the advantages of authorizing the users of smaller-scale common-pool resources to adopt policies that regulate the use of these resources are:

- Local knowledge. Users who have lived and appropriated from a resource system over a long period of time have developed relatively accurate mental models of how the biophysical system itself operates, since the very success of their appropriation efforts depends on such knowledge. They also know others living in the area well and what norms of behavior are considered appropriate.
- Inclusion of trustworthy participants. Users can devise rules that increase the probability that others are trustworthy and will use reciprocity. This lowers the cost of relying entirely on formal sanctions and paying for extensive guarding.
- Reliance on disaggregated knowledge. Feedback about how the resource system responds to changes in actions of users

is provided in a disaggregated way. Fishers are quite aware, for example, if the size and species distribution of their catch is changing over time.

- Better-adapted rules. Given the preceding, users are more likely to craft rules that are better adapted to each of the local common-pool resources than any general system of rules.
- Lower enforcement costs. Since local users have to bear the cost of monitoring, they are apt to craft rules that make infractions obvious so that monitoring costs are less. Further, by creating rules that are seen as legitimate, rule conformance will tend to be higher.
- Redundancy. The probability of failure throughout an entire region is greatly reduced by the establishment of parallel systems of rule making, interpretation, and enforcement.

There are, of course, limits to all ways of organizing the governance of common-pool resources. Among the limits of a highly decentralized system are:

- Some users will not organize. Although the evidence from the field is that many local users do invest considerable time and energy into their own regulatory efforts, other groups of users do not do so. There appear to be many reasons why some groups do not organize, including the presence of low-cost alternative sources of income and, thus, a reduced dependency on the resource, considerable conflict among users along multiple dimensions, lack of leadership, and fear of having their efforts overturned by outside authorities.
- Some self-organized efforts will fail. Given the complexity of the task involved in designing rules, some groups will select combinations of rules that generate failure instead of success. They may be unable to adapt rapidly enough to avoid the collapse of a resource system.
- Local tyrannies. Not all self-organized resource governance systems will be organized democratically or rely on the input of most users. Some will be dominated by a local leader or a power elite who only change rules that they think will give them further advantage. This problem is accentuated in locations where the cost of exit is particularly high and is reduced where users can leave when local decision makers are not responsible to a wide set of interests.
- Stagnation. Where local ecological systems are characterized by considerable variance, experimentation can produce severe and unexpected results, leading users to cling to systems that have worked relatively well in the past and to stop innovating long before they have developed rules likely to lead to better outcomes.
- Inappropriate discrimination. The use of identity tags is frequently an essential method for increasing the level of trust and rule conformance. However, tags based on ascribed characteristics can be the basis for excluding some individuals from access to sources of productive endeavor that has nothing to do with their trustworthiness.
- Limited access to scientific information. Although time and place information may be extensively developed and used, local groups may not have access to scientific knowledge concerning the type of resource system involved.

- Conflict among users. Without access to an external set of conflict-resolution mechanisms, conflict within and across common-pool resource systems can escalate and provoke physical violence. Two or more groups may claim the same territory and may continue to make raids on one another over a very long period of time.
- Inability to cope with larger scale common-pool resources. Without access to some larger scale jurisdiction, local users may have substantial difficulties regulating only a part of a larger scale common-pool resource. They may not be able to exclude others who refuse to abide by the rules that a local group would prefer to use. In this situation, local users have no incentives to restrict their own use and watch others take away all of the valued resource units that they have not appropriated.

The Capabilities of Polycentric Systems in Coping with Tragedies of the Commons

Many of the capabilities of a parallel adaptive system can be retained in a polycentric governance system. A polycentric system is one in which citizens are able to organize not just one but multiple governing authorities at differing scales (see McGinnis, 1999; Ostrom, 1997). Each unit may exercise considerable independence to make and enforce rules within a circumscribed scope of authority for a specified geographical area. In a polycentric system, some units are general-purpose governments and others may be highly specialized. Self-organized resource governance systems, in such a system, may be special districts, private associations, or parts of a local government. These are nested in several levels of general-purpose governments that also provide civil, equity, and criminal courts.

In a polycentric system, the users of each common-pool resource would have some authority to make at least some of the rules that are related to how that particular resource will be utilized, and thus would achieve most of the advantages of utilizing local knowledge, and the redundancy and rapidity of a trial-and-error learning process. However, problems associated with local tyrannies and inappropriate discrimination can be addressed in larger, general-purpose governmental units that are responsible for protecting the rights of all citizens and for the oversight of appropriate exercises of authority within smaller units of government. It is also possible to make a more effective blend of scientific information with local knowledge where major universities and research stations are located in larger units but have a responsibility to relate recent scientific findings to multiple smaller units within their region. Because polycentric systems have overlapping units, information about what has worked well in one setting can be transmitted to others who may try it out in their settings. Associations of local resource governance units can be encouraged to speed up the exchange of information about relevant local conditions and about policy experiments that have proved particularly successful. And, when small systems fail, there are larger systems to call on – and vice versa.

Polycentric systems are themselves complex adaptive systems without one central authority dominating all of the

others. Thus, there is no guarantee that such systems will find the optimal combination of rules at diverse levels that are optimal for any particular environment. In fact, one should expect that all governance systems will be operating at less-than-optimal levels, given the immense difficulty of fine-tuning any very complex, multitiered system.

In the US, there are many examples of dynamic, polycentric resource governance systems that display strong evidence of high performance. One example is the Maine lobster fishery, which is noteworthy because of the long-term, complementary roles adopted by both local and state governance systems. Maine is organized into riparian territories along most of the coast. Boundary rules and many of the day-to-day fishing regulations are organized by “harbor gangs”.

In order to go fishing at all, one must become a member of a harbor gang, the group of fishermen who go lobstering from a single harbor. Once one has gained admittance into such a group, one can only set traps in the traditional territory of that particular harbor gang. Members of harbor gangs are expected to obey the rules of their gang concerning fishing practices, which vary somewhat from one part of the coast to another.

There is strong statistical evidence that the territorial system, which operates to limit the number of fishers exploiting lobsters in each territory, helps to conserve the lobster resource (Acheson *et al.*, 1998: 400).

At the same time, the state of Maine has long established formal laws that protect the breeding stock and increase the likelihood that regeneration rates will be high.

At present, the most important conservation laws are minimum and maximum size measures, a prohibition against catching lobsters with eggs, and a law to prohibit the taking of lobsters which once had eggs and were marked – i.e., the ‘V-notch’ law (Acheson *et al.*, 1998: 400).

Neither the state nor any of the harbor gangs has tried to limit the quantity of lobster captured. The state does not make any effort to limit the number of fishers since this is already done at a local level. However, the state has been willing to intercede when issues exceed the scope of control of local gangs. In the late 1920s, for example, when lobster stocks were at very low levels and many local areas appear to have had substantial compliance problems, the state took a number of steps – including threats to close the fishery – that supported informal local enforcement efforts. By the late 1930s, compliance problems were largely resolved and stocks had rebounded (although it cannot be shown that these two results are related, just correlated).

Recently, in response to changes that were breaking down the harbor gang system, the state formalized the system by dividing the state into zones with democratically elected councils. Each council was given authority over rules that have principally local impacts – trap limits, days and times fished, and so on. Interestingly, the formalization of local zones was followed, almost immediately, by the creation of an informal council of councils to address problems at a greater than local scale. It is expected that this council of councils will be formalized soon.

Today the state uses only approximately six patrol officers on the water to police the activities of 6800 lobstermen, all the other fisheries, and coastal environmental laws. Since the early 1990s, the lobster fishery has been growing substantially with increased yields. At the same time, there is strong evidence that the number of females of reproductive age in Maine waters is very large and that the recruitment will continue at a high level (Wilson *et al.*, 2007).

Conclusions

Widespread concern for conserving biodiversity is a reflection of the inherent and ecological value of such diversity. Those who advocate the necessity of sustaining biodiversity have frequently called for policy reforms that reduce the diversity of institutional arrangements for governing and managing complex common-pool resources. Yet, as Ashby long ago established, regulators need as much variety in their response capabilities as the systems they are regulating. To achieve biodiverse resource systems, we need to protect and enhance the institutional diversity of evolved governance regimes within the context of a broader multitiered, polycentric governance regime.

Complexity Versus Diversity

Glossary

Biotic interaction When the growth or behavior of one species affects those of another species; such interactions can be antagonistic (e.g., competition for limiting resources, predation, herbivory, or parasitism) or facilitatory (e.g., pollination or other forms of mutualism).

Community Set of coexisting species in an ecosystem.

Food web A set of trophic relationships among species in a community; schematically, the pattern often resembles a web of species each connected by trophic interactions with other species.

Functional dependency Dependency of one species on another to complete a particular ecosystem process or function; an example would be the dependency of plants on decomposers and decomposers on plants to recycle nutrients.

Phylogeny A pattern of evolutionary descent among species, generally illustrated as a tree in which nodes

represent common ancestors and the lengths of branches represent time since divergence; time since divergence is generally assumed to correlate with genetic relatedness.

Process intricacy Complexity of temporal or spatial patterns of ecological processes such as population dynamics or production.

Structural intricacy Complexity of patterns of links or connections among species in a community that are created by biotic interactions, shared pathways of nutrient and energy flow, or phylogenetic relationships.

Trophic interaction Feeding relationship between two species; these include predation, herbivory, parasitism, bacterivory, frugivory, or any other interaction that involves individuals of one species consuming individuals or parts of individuals from another species; trophic interactions represent a subset of all biotic interactions in a community.

Ecological complexity and biological diversity are often presumed to be strongly correlated or even synonymous with one another, but there is no necessary relationship between these terms. Ecological complexity is a scale by which we compare ecosystems. At one end of the scale, systems that exhibit unpredictable behavior or many connections among its species (e.g., connected by biotic interactions such as predation, parasitism, facilitation, or competition, that influence the population dynamics or flow of energy and nutrients among species in an ecosystem) are considered “complex.” At the other end of the scale, systems that exhibit highly predictable behavior or consist of largely independent or unconnected species are considered “simple.” In contrast, biological diversity is a measure of the extent of genetic and phenotypic variation found within a community. Although these two characteristics of ecosystems are relatively distinct, they are, at a certain level, fundamentally related. For example, the number of potential connections (i.e., potential complexity) is a function of the number of species (i.e., diversity), even if the actual number of connections among species (i.e., realized complexity) may range from none to the full complement of possible connections (i.e., every species is connected to every other species).

Widespread changes in diversity experienced by most ecosystems have generated considerable interest in quantifying complexity and assessing whether current changes are affecting levels of ecological complexity in natural ecosystems. The resolution of issues surrounding the relationship between complexity and diversity is an active area in contemporary ecological research.

The Complexity of Ecologically Diverse Systems

Hence, if certain insectivorous birds (whose numbers are probably regulated by hawks or beasts of prey) were to increase in Paraguay, the flies would decrease – then cattle and horses would become feral, and this would certainly greatly alter (as indeed I have observed in parts of South America) the vegetation: this again would largely affect the insects; and this, as we just have seen in Staffordshire, the insectivorous birds, and so onwards in ever increasing circles of complexity.

– Charles Darwin, 1859

It is reasonable to believe that in following the numbers of orders in the fossil record we are indeed following the approximate overall course of ecological complication and diversification even though in a necessarily loose way.

– Simpson, 1969

Roughly speaking, we here take complexity to be measured by the number and nature of the individual links in the food web.

– May, 1974

The complexity of a system is in the eye of the beholder. It is measured by how well we understand causes, expect behaviours

and, in praxis, achieve purposes. Hence, large numbers of variables, nonlinear relationships among them, and the open nature of a system are important only to the degree they present barriers to understanding.

– Holling, 1985

The Complexity of Nature and the Entangled Bank

Darwin provided us with a wonderful metaphor for what is intuitively meant by “ecological complexity” in his famous closing passage to *The Origin of Species*. In this passage, Darwin envisioned a riverbank teeming with a diverse and entangled array of organisms all involved in a complex web of biotic interactions. At the heart of this seemingly complex system, however, lies evolutionary and ecological processes that produce and maintain such remarkable diversity. For Darwin, biodiversity and the complexity that accompanies it are what distinguish nature from the inanimate features and processes of our world.

The entangled bank metaphor highlights two main ingredients of ecological complexity. First, there is biological diversity itself, with a clear implication that greater diversity provides a greater potential for complexity. Second, and more importantly, there is the web of interactions among species, with an equally clear implication that more complex webs (e.g., greater numbers and kinds of biotic interactions among species) are indicative of more diverse communities. Biotic interactions, however, describe only one way in which species are linked to one another. We can expand our entangled bank metaphor to include others linkages or relationships among species such as phylogenetic relationships, functional relationships, and exchanges of material and energy among species.

This entangled bank metaphor also highlights two distinct meanings of complexity. First, complexity refers to the intricacy of the pattern of linkages among species. This is the meaning used in many studies that have related ecological complexity to ecological stability beginning with MacArthur’s (1955) classic work examining ecosystem structure and May’s (1974) work on ecological communities, to innumerable studies that examine food-web and community structure (McCann, 2000) or more generally the topology of ecological networks (Jordán and Scheuring, 2004; Montoya *et al.*, 2006). The second meaning applied to the term complexity is when nature defies easy characterization and cannot be reduced to a finite set of processes and principles that govern its order. This second meaning is used from the “macroecological” perspective (Brown, 1995), the hierarchical perspective of nature (O’Neill *et al.*, 1986), the perspective of nature as complex adaptive system (Levin, 2005), or when nature is viewed as a self-organizing system (Allen and Holling, 2010).

Figure 1 illustrates these different kinds of complexities. The top row of Figure 1 shows the dynamics of an ecosystem or evolutionary process as an example of an ecosystem property that may exhibit simple or complex behavior. This process could be production, decomposition, or any other process representing the aggregate activities of species in the community. It could also be an evolutionary process such as origination or extinction. The remainder of Figure 1 shows three fundamental kinds of linkages among species in communities:

ecological networks (i.e., the network of biotic interactions among species), phylogenetic structure or the pattern of phylogenetic relationships among species, and functional structure or the pattern of functional dependencies among species.

The pattern of temporal or spatial variation of processes is known as process intricacy. The pattern of linkages, whether referring to an ecological network, phylogenetic structure, or functional structure, is known as structural intricacy.

Whether considering process or structural intricacy, exhibiting either highly ordered states or highly irregular or disordered states is considered complex. As shown in Figure 1, a temporal pattern for a specific ecological or evolutionary process that exhibits highly ordered, predictable, repeated series of oscillations would be considered complex. Yet a highly irregular, unpredictable, chaotic pattern of oscillation would also be considered complex when compared to a simple, mildly oscillating process. Similarly, Figure 1 shows that a pattern of biotic interactions in which every species is linked to every other species in the community by exactly the same kind of interaction with exactly the same strengths of interactions creates a symmetrical, highly ordered structure that would be considered complex. At the same time, a community that has a jumbled network of biotic interactions that vary in type and strength would also be considered complex when compared to a simple set of independent, noninteracting species. Finally, if all species contribute identically to ecosystem function, the functional structure is simple, but if species contribute in different ways, ranging from partially redundant to completely unique, then the structure is complex.

Although ecological complexity is difficult to define precisely given the many different ways the term is used, when we consider the basic elements of ecological complexity it becomes apparent that diversity is not a necessary part of the definition of complexity. Note in Figure 1, for example, that all nine structures shown are made up of six species. In spite of having the same number of species, these structures differ quite dramatically in complexity.

Despite the fact that diversity is not a necessary part of the definition of complexity, diversity and complexity are related in an elementary yet fundamental way. Few would debate that extremely depauperate ecosystems such as monoculture plantations of bananas are less complex than the extremely species-rich tropical rain forests they replaced, but for the bulk of ecological communities that lie somewhere between these extremes of biodiversity, determining just how complex a given system is can be quite difficult. For example, if a community contained 25 species of grasses whereas another contained only 10 species, but was made up of a mixture of three grasses, four forbs, and three shrubs, which community would be more complex? If a community consisted of 25 non-interacting species and another contained five species involved in a complex web of interactions, which would be more complex? If two communities each contained 10 species, but one exhibited chaotic dynamics whereas the other hovered close to a constant number of individuals per year in spite of repeated perturbations, which would be more complex?

Another way to look at the problem is to plot, simply for illustrative purposes, complexity against biodiversity as done in Figure 2. Aside from the trivial points where there is no

Figure 1 Simplicity and complexity in ecological systems. Dynamics are illustrated as temporal patterns in an ecological or evolutionary process, such as production, standing biomass, energy or nutrient flow, or rates of diversification. Community or network structure is illustrated as the number, type (e.g., competition or facilitation, shown as $-$ or $+$, respectively), strengths (thickness of arrows), and arrangement of interactions (arrows) among species (circles). If the only interactions portrayed are trophic interactions, then the network diagram would be that of a food web. Phylogenetic structure is illustrated as phylogenetic trees in which every two species share a common ancestor. The vertical lengths of branches indicate distances, assumed to be a measure of genetic similarity or time since divergence. The complex phylogenies of more distantly related species contain more genetic information than would be found in the simple phylogeny of many closely related species. Functional complexity is illustrated as species whose contributions to ecosystem processes are either largely dependent (serially linked) on the activities of other species or exhibit a diverse array of interdependencies among one another. A simple system is one in which all species contribute to the functioning of an ecosystem in the same way (parallel redundancy) such that the loss of a species from a system does not affect its functioning.

diversity, and therefore no ecological complexity, and where there is some diversity and there is some complexity, a variety of relationships could be drawn between the two points depending on one's perspective or experience. That is, complexity and diversity could either increase hand-in-hand or show any possible relationship that is bounded by a positive, asymptotic relationship between diversity and complexity on one end and an exponential relationship between diversity and complexity on the other end (see Figure 2). Of interest

would be whether some general relationship could be described or whether every ecosystem would show a unique relationship. If the latter is true, then knowing a system's diversity would provide no means for predicting its complexity and whatever ecological behaviors might be a function of complexity.

Because ecological complexity is believed to be an important part of biologically diverse ecosystems and because diversity is currently rapidly declining, the role of ecological

Figure 2 The potential relationships between complexity and biodiversity. Three possible relationships are shown. (I) The upper bound represented by an asymptote in complexity as biodiversity increases. (II) A linear relationship in which biodiversity is a direct measure of complexity in an ecosystem. (III) The lower bound represented by an exponential increase in complexity as diversity increases. Curve II represents the common perception of biodiversity and complexity being intimately related, but I and III represent the actual bounds for where the true relationship for a given ecosystem lies.

complexity is of considerable concern to ecologists. Does biodiversity loss mean loss of ecological complexity? If so, what are the ecological consequences of losing ecological complexity? This article reviews ecological complexity, its definition, its measurement, its relationship to biodiversity, and what is known about its role in ecosystem functioning.

Concepts and Definitions

In 2004, the journal *Ecological Complexity* became the first scientific journal focused, as its name implies, on ecological complexity. Li (2004), the managing editor, on behalf of the editorial board, provided the following definition of ecological complexity:

"... the complex interplay between all living systems and their environment, and emergent properties from such an intricate interplay. The concept of ecological complexity stresses the richness of ecological systems and their capacity for adaptation and self-organization. The science of ecological complexity seeks a truly quantitative and integrative approach towards a better understanding of the complex, nonlinear interactions (behavioral, biological, chemical, ecological, environmental, physical, social, cultural) that affect, sustain, or are influenced by all living systems, including humans."

In contrast, the most widely used definition of biodiversity is taken from Article 2 of the 1992 United Nations Convention on Biological Diversity (CBD) which defines biodiversity as:

"...the variability among living organisms from all sources including, *inter alia*, terrestrial, marine and other aquatic systems and the ecological complexes of which they are part; this includes diversity within species, between species and of ecosystems."

Li does not refer to biodiversity in his definition of ecological complexity nor does the CBD refer to ecological complexity in its text. Li does, however, refer to the richness (i.e., diversity) of ecological systems which is related to the CBD's reference to the variability among ecological complexes. The two definitions thus overlap in seeing complexity and diversity as relevant parts of each of their definitions.

Chapman (1985), in his review of a symposium on the concept of complexity, identified four distinct meanings of "complex" used in the conference and in the literature. First, there is what Chapman called "complication," or the process by which a system becomes naturally complex, but such complexity is ultimately "reducible" to fundamental principles or mechanisms. Second, there is "complication," which, like complication, concerns reducible systems, but involves purposeful design (e.g., a watch or a banana plantation has a different kind of complexity than the solar system or a tropical rain forest). Third, there is "complexification," which concerns irreducible systems (systems that are not composites of simpler parts). Finally, the fourth usage is "complexity" itself, which is simply a state of uncertainty concerning whether a system is reducible or not (irrespective of it being natural or of purposeful design). These decidedly ugly terms are not likely to catch on, but they do point to the variety of ways that ecologists, like other scientists, use complexity.

Community, Phylogenetic, and Functional Complexity

Typically, the web of interactions within a community, characterized by the number, nature, strengths, and structural pattern of biotic interactions among species, is often what is treated as ecological complexity. This can be the web of all interactions (community web, including competition, facilitation, parasitism, predation, and other interactions) or a subset of the community web, such as just trophic or feeding interactions (food web, including predation, herbivory, disease, or other consumer–resource species interactions).

In contrast to community complexity, however, phylogenetic complexity may be of interest when a community contains a diverse array of taxa. From the perspective of systematists or paleontologists, simply having many species that are phylogenetically diverse is evidence for complexity (Raven, 1996). A system of 15 species of grasses from the same genus might be considered less phylogenetically complex than a system of 10 species from 10 genera of grasses, which in turn might be less complex than a system with five species each from a different plant family.

Finally, complexity of an ecological system may be tied to its functioning as a biogeochemical system rather than to its population or biomass dynamics. That is, the flow of nutrients and energy through the system may be of interest rather than the dynamics of the many populations found within it. Note that ecosystems function in the sense that they exhibit activity or processes such as nutrient and energy flow. "Function" need not imply purpose or design.

From the foregoing, it is apparent that ecological complexity is a composite feature of ecosystems consisting of an extraordinary number of different factors, including population, phylogenetic, and functional characteristics of the

species in the community. The full measure of the complexity of a single ecosystem would therefore include a large number of factors, most of which are difficult to quantify. In general, increases in any of the properties listed in **Table 1**, whether associated with structural or process intricacy, tend to increase ecological complexity, whereas decreases tend to simplify them. **Table 1** demonstrates that measures of biotic diversity per se, such as species richness or evenness, are likely to be inadequate measures of complexity, though they may serve as crude proxy measures. The next section considers some basic measures of complexity, but not surprisingly, it will be evident that such measures of complexity generally deal with only single dimensions of complexity.

Measures and Consequences of Ecological Complexity

Measures of Complexity

Because complexity is a scale by which we compare communities and ecosystems, quantifying or measuring complexity is important in providing accurate means of making comparisons. Measuring complexity, however, is difficult because complexity is difficult to define. **Boulding (1985)** nicely

described the problem at a United Nations conference held in Tokyo on the theory of complexity. He stated:

"Complexity is a very complex concept, which is not altogether surprising. We do have a vague concept of it as a somewhat linear property, both of structures and processes, in which we make judgments of "more" or "less." I am pretty sure I am more complex than an amoeba... . Exact measurement of the concept eludes us and probably always will, for although we do make these estimations of it in terms of more or less, it represents a highly multi-dimensional reality that cannot be reduced to a linear measure."

In spite of the obvious difficulties **Boulding** outlined, ecologists and evolutionary biologists have nevertheless provided a number of measures of complexity, which are reviewed in the following sections. These measures can be used in conjunction with measures of diversity to assess the relationship between complexity and diversity.

Measures of Community Complexity

Measures of ecological complexity are closely allied with measures of diversity, which reinforces the common practice among ecologists of treating biodiversity and complexity as one and the same. At its simplest, one might consider diversity to simply be the number of species (S), or species richness.

Table 1 Measures of ecological complexity

<i>Term</i>	<i>Measure</i>
Structural intricacy	Numbers of populations
	Numbers of species
	Numbers of biotic interactions
	Kinds of interactions
	Strengths of interaction
	Higher order effects
	Indirect effects
	Connectedness
	Number of patches
	Arrangement of patches
	Immigration probabilities
	Emigration probabilities
	Number of functional groups
	Number of functionally singular species (inverse of redundancy)
	Number of links among functional groups
	Number of compound functional groups (e.g., omnivores)
	Distribution of species' functional traits (means and variances)
	Covariance among species' functional traits
	Distances or overlaps among species' functional traits
	Trait-space volume occupied by species in an ecosystem
Process intricacy	Phylogenetic distances among species
	Phylogenetic moment
	Invasibility
	Stability (Resistance, Resilience, Variability)
	Predictability
	Reliability
	Degree of nonlinearity
	Succession
	Population growth
	Ecosystem processes
	Extinction
	Speciation

Such a measure is often felt to be inadequate because it does not reflect differences in commonness and rarity nor the degree of connectedness among species. Thus, many other measures of diversity are used that attempt to take linkages or potential linkages into account. For example, the Shannon–Weaver index (H) considers both species richness and the relative abundances of species (evenness) as the important components of diversity. H quantifies diversity by assuming that richness and evenness directly represent the potential number of community configurations that a particular assemblage of species can produce. The original index quantified information, summing logged probabilities of a system having particular configurations.

The configuration of a community is seldom known, let alone the variety of possible configurations it can occupy or the probabilities of taking on these configurations. One therefore uses proportional abundances (p) of species as a means of approximating probabilities of configurations, a strategy that some consider fairly unsound.

The formula using this approach is

$$H = - \sum_{i=1}^S p_i \ln p_i \quad [1]$$

where i refers to the i th species in the community.

A related measure of potential complexity that compares the full potential with the realized potential for configurations is called connectivity (C), or the proportion of actual interactions (links or connections) to total possible interactions, which is distinct from food-web connectance (see later). The formula for connectivity is

$$C = \sum_{i \neq j} a_{ij} p_i p_j / \sum_{i \neq j} p_i p_j \quad [2]$$

in which p is the probability of a species being present, and a_{ij} is the probability of interaction when two individuals, each from a different species (i and j), encounter one another. In reality, identifying interactions in biological communities is very difficult and cannot be deduced from abundance data. Indeed, [Margalef and Gutiérrez \(1983\)](#) explored connectance by examining components and “interactions” in functional plans for construction toys because information of equivalent clarity from real communities was unavailable.

The Shannon formalism serves as the basis for the preceding and other measures of complexity and diversity, but this practice is questionable. The Shannon formalism quantifies complexity by estimating an upper bound for the number of configurations possible for a given set of entities as if all configurations would be functional. In reality, however, rules of assembly ultimately determine the actual limits of information that a set of entities can store and retrieve efficiently. For example, if one had a box of 26 unique letters (i.e., A–Z), each equally abundant, and a box of four unique nucleotides, each equally abundant, the Shannon formalism would consider the box of letters to have a greater capacity to store and retrieve information. Assembly rules for letters, however, must be followed to produce sentences containing useful information just as assembly rules for nucleotide sequences must be followed to produce useful proteins. It is quite possible that four nucleotides could code for a greater diversity of proteins

in nature than 26 letters can code for words in English, the difference being attributable to the rules used in each system. Without knowing these rules, it is difficult to assess the actual information content for a collection of entities such as letters, nucleotides, or species. Although assembly rules for nucleotides and letters in human languages are well understood, assembly rules for species in communities, although well studied, are still poorly understood.

Appraisals of complexity based on static patterns of the distribution and abundance of species ((1) and (2)) ignore flows of energy or nutrients and the dynamics of interacting populations, all of which are considered key elements of community complexity (see [Figure 1](#)). [Rutledge et al. \(1976\)](#) adapted approaches based on information theory, as discussed earlier, to consider flows among species within a community. Their approach usefully distinguishes between and quantifies both flavors of complexity – structured versus disordered patterns of flows among species.
